A topological approach to Cheeger-Gromov universal bounds for von Neumann rho-invariants

Jae Choon Cha

Abstract. Using deep analytic methods, Cheeger and Gromov showed that for any smooth $(4k - 1)$-manifold there is a universal bound for the von Neumann $L^2$ $\rho$-invariants associated to arbitrary regular covers. We present a new simple proof of the existence of a universal bound for topological $(4k - 1)$-manifolds, using $L^2$-signatures of bounding $4k$-manifolds. For $3$-manifolds, we relate the universal bound to triangulations, mapping class groups, and framed links, by giving explicit estimates. We show that our estimates are asymptotically optimal. As an application, we give new lower bounds of the complexity of $3$-manifolds which can be arbitrarily larger than previously known lower bounds. As ingredients of the proofs which seem interesting on their own, we develop a geometric construction of efficient $4$-dimensional bordisms of $3$-manifolds over a group, and develop an algebraic notion of uniformly controlled chain homotopies.

1. Introduction and main results

In [CG85], Cheeger and Gromov studied the $L^2$ ρ-invariant $\rho^2(M, \phi) \in \mathbb{R}$, which they defined for a closed $(4k - 1)$-dimensional Riemannian manifold $M$ and a homomorphism $\phi: \pi_1(M) \to G$ into a group $G$. Briefly speaking, $\rho^2(M, \phi)$ is the difference of the $\eta$-invariant of the signature operator of $M$ and the $L^2 \eta$-invariant of that of the $G$-cover of $M$ which is defined using the von Neumann trace. As a key ingredient of their study of topological invariance, Cheeger and Gromov showed that there is a universal bound of the $L^2 \eta$-invariants of arbitrary coverings of $M$, by using deep analytic methods. Equivalently, there is a universal bound of the Cheeger-Gromov $\rho$-invariants of $M$:

**Theorem 1.1** (Cheeger-Gromov [CG85]). For any closed smooth $(4k - 1)$-manifold $M$, there is a constant $C_M$ such that $|\rho^2(M, \phi)| \leq C_M$ for any homomorphism $\phi: \pi_1(M) \to G$ into any group $G$.

In this paper we develop a topological approach to the Cheeger-Gromov universal bound $C_M$. Our method presents a topological proof of the existence, and gives new topological understanding of the universal bound with applications to low dimensional topology. In particular, we reveal an intriguing relationship of the Cheeger-Gromov $\rho$-invariant and the complexity theory of 3-manifolds.

In this section, we discuss some backgrounds and motivations, state our main results and applications, and introduce some ingredients of the proofs developed in this paper, which seem interesting on their own.

As a convention, we assume that manifolds are compact and oriented unless stated otherwise.

1.1. Background and motivation

A known approach to $\rho$-invariants is to use a standard index theoretic fact that if a $(4k - 1)$-manifold $M$ is the boundary of a $4k$-manifold $W$ to which the given representation of $\pi_1(M)$ extends, then the $\rho$-invariant of $M$ may be computed as a signature defect of $W$. For the von Neumann $L^2$ case, as first appeared in the work of Chang and Weinberger [CW03], we can recast this index theoretic computation to provide a topological definition: for any $M$ and $\phi$, $\rho^2(M, \phi)$ can be defined as a topological $L^2$-signature defect of a certain bounding manifold, in the topological category as well as the smooth category. This is done using a theorem of Kan and Thurston that any group embeds into an acyclic group [KT76] and using the invariance of the von Neumann trace under composition with a monomorphism. Also, instead of Hilbert modules and $L^2$-(co)homology, we can use standard homology over the group von Neumann algebra, by employing the $L^2$-dimension theory of Lück [Lüc98, Lüc02]. For the reader’s convenience, we provide precise definitions and detailed arguments in Section 2.1 for topological $(4k - 1)$-manifolds.

Although the Cheeger-Gromov $\rho$-invariant can be defined topologically, known proofs of the existence of a universal bound are entirely analytic [CG85, Ram93], and provide hardly any information on the topology of $M$. From this a natural question arises:

**Question 1.2.** Can we understand the Cheeger-Gromov bound topologically?

This question is intriguing on its own, along the long tradition of the interplay between geometry and topology. Because of the deep analytic aspect, it has been regarded as a hard problem. Attempts to understand the Cheeger-Gromov bound using $L^2$-signature defects have failed (for instance see [CT07, p. 348]). The key reason is that the bounding $4k$-manifold used to define $\rho^2(M, \phi)$ in known arguments depends on the choice of $\phi$. 
Topological understanding of the Cheeger-Gromov bound is also of remarkable importance for applications, particularly to knots, links, and low dimensional manifolds. Since the work of Cochran, Orr, and Teichner on knot concordance [CO10], several recently discovered rich structures on topological concordance of knots and links, topological homology cobordism of 3-manifolds, and symmetric Whitney towers and gropes in 4-manifolds have been understood by using the Cheeger-Gromov invariant. The most general known obstructions from the Cheeger-Gromov invariant in this context are given as the amenable signature theorems in [CO12] Theorems 1.1 and 7.1 and [Cha14] Theorem 3.2. In many applications, it is essential to control $\rho^{(2)}(M, \phi)$ for certain homomorphisms $\phi$. In [CT07], Cochran and Teichner first introduced the influential idea that the Cheeger-Gromov bound is extremely useful for this purpose. Since then, the Cheeger-Gromov bound has been used as a key ingredient in various interesting works (some of them are listed at the end of Section 1.2). It is known that many existence theorems in these works could be improved to give explicit examples if we had a better understanding of the Cheeger-Gromov bound. A key question arising in this context is the following: if $M$ is the zero surgery manifold of a given knot $K$, how large is $C_M$? For instance, for the simplest ribbon knot $K = 6_1$ (stevedore’s knot), is $C_M$ less than a billion? In spite of these desires, almost nothing beyond its existence was known about the Cheeger-Gromov bound.

1.2. Main results on the Cheeger-Gromov universal bound

As our first result, we present a topological proof of the existence of the Cheeger-Gromov bound that directly applies to topological manifolds, based on the $L^2$-signature defect approach.

**Theorem 1.3.** For any closed topological $(4k-1)$-manifold $M$, there is a constant $C_M$ such that $|\rho^{(2)}(M, \phi)| \leq C_M$ for any homomorphism $\phi: \pi_1(M) \to G$ into any group $G$.

The outline of the proof is as follows. As the heart of the argument, we show that for an arbitrary $(4k-1)$-manifold $M$, there is a single $4k$-manifold $W$ with $\partial W = M$ from which every Cheeger-Gromov invariant $\rho^{(2)}(M, \phi)$ of $M$ can be computed as an $L^2$-signature defect. Once it is proven, it follows that twice the number of 2-cells in a CW structure of $W$ is a Cheeger-Gromov bound, by using an observation that any $L^2$-signature of $W$ is not greater than the number of 2-cells. A key ingredient used to show the existence of $W$ is a functorial embedding of groups into acyclic groups due to Baumslag, Dyer, and Heller [BDH80]. More details are discussed in Section 2.

Beyond giving a topological proof of the existence, our approach provides us a new topological understanding of the Cheeger-Gromov bound. For 3-manifolds, we relate the Cheeger-Gromov bound to the fundamental 3-manifold presentations: triangulations, Heegaard splittings, and surgery on framed links, by giving explicit estimates in terms of topological complexities defined from combinatorial, group theoretic, and knot theoretic information respectively.

Regarding triangulations, we consider the following natural combinatorial measure of how much complicated a 3-manifold is topologically. In this paper, a triangulation designates a simplicial complex structure.

**Definition 1.4.** The simplicial complexity of a 3-manifold $M$ is the minimal number of 3-simplices in a triangulation of $M$.

The following result relates the combinatorial data to the Cheeger-Gromov bound, which was analytic, via a topological method.
Theorem 1.5. Suppose $M$ is a closed 3-manifold with simplicial complexity $n$. Then
\[ |\rho^{(2)}(M, \phi)| \leq 363090 \cdot n \]
for any homomorphism $\phi: \pi_1(M) \to G$ into any group $G$.

In the next subsection, we will discuss an application of Theorem 1.5 to the complexity theory of 3-manifolds. In the last two subsections of this introduction, we will introduce two key ingredients of the proof of Theorem 1.5 (and Theorems 1.8 and 1.9 below), which are essentially topological and algebraic respectively.

The linear bound given in Theorem 1.5 is asymptotically optimal. To state it formally, we define the “most efficient” Cheeger-Gromov bound as a function $B_{sc}(n)$ in the simplicial complexity $n$, as follows:
\[ B_{sc}(n) = \sup \left\{ |\rho^{(2)}(M, \phi)| \middle| M \text{ has simplicial complexity } n \text{ and } \phi \text{ is a homomorphism of } \pi_1(M) \right\} \]

Theorem 1.5 tells us that $B_{sc}(n)$ is at most linear asymptotically. In other words, $B_{sc}(n) \in O(n)$; recall that $f(n) \in O(g(n))$ if $\limsup_{n \to \infty} |f(n)/g(n)| < \infty$. In our case, by Theorem 1.5, we have
\[ \limsup_{n \to \infty} \frac{B_{sc}(n)}{n} \leq 363090. \]

Also, recall that the small $o$ notation formalizes the notion that $f(n)$ is strictly smaller than $g(n)$ asymptotically, that is, $f(n)$ is dominated by $g(n)$: we say $f(n) \in o(g(n))$ if $\lim_{n \to \infty} |f(n)/g(n)| = 0$. As another standard notation, we say that $f(n) \in \Omega(g(n))$ if $f(n)$ is not dominated by $g(n)$, that is, $\limsup_{n \to \infty} |f(n)/g(n)| > 0$. We prove the following result in Section 7.3.

Theorem 1.6. $B_{sc}(n) \in \Omega(n)$. In fact, $\limsup_{n \to \infty} \frac{B_{sc}(n)}{n} \geq \frac{1}{288}$.

Recall that any closed 3-manifold $M$ admits a Heegaard splitting, namely a decomposition of $M$ into two handlebodies. A Heegaard splitting is determined by a mapping class $h$ in the mapping class group $\text{Mod}(\Sigma_g)$ of a surface $\Sigma_g$ of genus $g$. (For a more precise description, see the beginning of Section 6.3.) A natural way to measure its complexity is to consider the word length of $h$ in the group $\text{Mod}(\Sigma_g)$. It is well known that $\text{Mod}(\Sigma_g)$ is finitely generated by standard Dehn twists; Lickorish showed that $\text{Mod}(\Sigma_g)$ is generated by the $\pm 1$ Dehn twists about the $3g - 1$ curves $\alpha_i$, $\beta_i$, and $\gamma_i$ shown in Figure 1 [Lic62].

![Figure 1. Lickorish’s Dehn twist curves.](image)

Definition 1.7. The Heegaard-Lickorish complexity of a closed 3-manifold $M$ is defined to be the minimal word length, with respect to the Lickorish generators, of a mapping class $h \in \text{Mod}(\Sigma_g)$ which gives a Heegaard splitting of $M$.
We remark that the Heegaard-Lickorish complexity tells us more delicate information than the Heegaard genus, in the sense that the difference of the Heegaard-Lickorish complexities of two 3-manifolds with the same Heegaard genus can be arbitrarily large, whereas the Heegaard genus is bounded by twice the Heegaard-Lickorish complexity (see Lemma 6.7).

The following result relates the above geometric group theoretic data to the Cheeger-Gromov bound.

**Theorem 1.8.** Suppose $M$ is a closed 3-manifold with Lickorish-Heegaard complexity $\ell$. Then

$$|\rho^{(2)}(M, \phi)| \leq 251258280 \cdot \ell$$

for any homomorphism $\phi: \pi_1(M) \to G$ into any group $G$.

Our next result is about surgery presentations of 3-manifolds. It is well known that any 3-manifold is obtained by surgery along a framed link in $S^3$, that is, Dehn surgery with integral coefficients. For a framed link $L$ in $S^3$, let $n_i(L) \in \mathbb{Z}$ be the framing on the $i$th component $L_i$, that is, $n_i(L) = \text{lk}(L_i, L'_i)$ where $L'_i$ is the parallel copy of $L_i$ taken along the given framing. We define $f(L) = \sum_i |n_i(L)|$. We denote by $c(L)$ the crossing number of a link $L$ in $S^3$, that is, the minimal number of crossings of a planar diagram of $L$.

**Theorem 1.9.** Suppose $M$ is a 3-manifold obtained by surgery along a framed link $L$ in $S^3$. Then

$$|\rho^{(2)}(M, \phi)| \leq 69713280 \cdot c(L) + 34856640 \cdot f(L)$$

for any homomorphism $\phi: \pi_1(M) \to G$ into any group $G$.

Similarly to Theorem 1.6, we show that the linear bounds in Theorems 1.8 and 1.9 are asymptotically optimal. We omit details in this introduction; for formal statements and proofs, see Definition 7.7, Theorem 7.8, and related discussions in Section 7.2.

**Remark 1.10.** While the linear bounds in Theorems 1.5, 1.8, and 1.9 are asymptotically optimal, it seems that the coefficients in these linear bounds can be improved. Although we do not address it in this paper, finding optimal or improved coefficients seems to be an interesting problem.

As an application, our explicit universal bounds for the Cheeger-Gromov invariants are useful in improving several recent results in low dimensional topology related to knots, links, 3-manifolds, and their 4-dimensional equivalence relations. For instance, in light of Theorem 1.9 (and Theorem 6.5 in the body of the paper, which is another similar result), now the proofs of the following existence results of various authors can give us explicit examples of: (i) knots of infinite order in the graded quotient of the Cochran-Orr-Teichner $n$-solvable filtration, and similarly for the grope filtration [CT07, Theorems 1.4 and 4.2], [CHL09] Theorems 9.1 and 9.5 and Corollary 9.7; (ii) slice knots which are algebraically doubly slice but nontrivial in the graded quotient of the double $n$-solvable filtration (and consequently not doubly slice) [Kim06] Theorem 1.1; (iii) knots whose iterated Bing doubles are in $n$-solvable but not $(n+1)$-solvable (and consequently not slice) [CHL08], Corollaries 5.2 and 5.3 and Theorem 5.16; (iv) 2-torsion knots generating $(\mathbb{Z}_2)^\infty$ in the graded quotients of the $n$-solvable filtration [CHL11] Theorems 5.5 and 5.7 and Corollary 5.6; (v) non-concordant knots obtained from the same knots by infection using distinct curves [Fra13] Theorem 3.1 and Corollaries 3.2 and 3.3; (vi) knots which generate $\mathbb{Z}^\infty$ in the graded quotients of the $n$-solvable filtration and have vanishing Cochran-Orr-Teichner PTFA signature obstructions [Chin] Theorems 1.4 and 4.11; (vii) links which are height $n$ grope concordant to but not height $n.5$ Whitney tower concordant to the Hopf link.
The following variation of the simplicial complexity is often considered: a pseudo-simplicial triangulation of a 3-manifold is defined to be a collection of 3-simplices whose faces are identified in pairs under affine homeomorphisms to give the 3-manifold as a quotient space. Similarly to Definition 1.4, the pseudo-simplicial complexity $c(M)$ of a 3-manifold $M$ is defined to be the minimal number of 3-simplices in a pseudo-simplicial triangulation. Following conventions in the literature, we call $c(M)$ the complexity of $M$. (cf. we use the terminology simplicial complexity in Definition 1.4 to avoid confusion.) In [Mat90], Matveev defines the notion of complexity using spines in a 3-manifold, which turns out to be equal to $c(M)$ except the case of $M = S^3$, $RP^3$, and $L(3,1)$, and develops some fundamental results.

Finding an efficient (pseudo-simplicial) triangulation is essential to several aspects of 3-manifold topology, from the normal surface theory initiated in the 1920’s by Kneser, to recent quantum invariants and computational approaches. Nonetheless, understanding the complexity for the general case remains as a difficult problem. While we easily obtain an upper bound from a triangulation, finding a lower bound has been recognized as a hard problem [Mat03, JRT13].

As an application of our results on the Cheeger-Gromov bound, we present new lower bounds of the complexity of 3-manifolds. For the simplicial complexity, note that Theorem 1.5 already told us that for any homomorphism $\phi$ of $\pi_1(M)$

$$\frac{1}{363090} \cdot |\rho^2(M, \phi)|$$

is a lower bound. Since the second barycentric subdivision of a pseudo-simplicial triangulation is a simplicial complex and since each tetrahedron in a pseudo-simplicial triangulation gives $(4!)^2 = 576$ tetrahedra in its second barycentric subdivision, we immediately obtain the following corollary of Theorem 1.5:

**Corollary 1.11.** If $M$ is a closed 3-manifold, then for any homomorphism $\phi$ of $\pi_1(M)$,

$$c(M) \geq \frac{1}{209139840} \cdot |\rho^2(M, \phi)|.$$
Theorem 1.12. There are 3-manifolds $M$ for which the lower bound for $c(M)$ in Corollary 1.11 is arbitrarily larger than the lower bound information from (i) the fundamental group and first homology $[MP01]$, (ii) the hyperbolic volume $[MPV09]$, and (iii) double covers and $\mathbb{Z}_2$ Thurston norm $[JRT09, JRT11, JRT13]$. In fact, there are 3-manifolds for which the lower bound in Corollary 1.11 grows linearly while the lower bounds in $[MP01], [MPV09], [JRT09, JRT11, JRT13]$ vanish or have logarithmic or square root growth. More details is discussed in Section 4.

As an infinite family of explicit examples, we consider lens spaces. In $[JRT09, JRT11]$, Jaco, Rubinstein, and Tillman determine the complexity of $L(n,1)$ with $n$ odd, it turns out that previously known lower bounds are not sharp even asymptotically. (For more details, see the discussion at the end of Section 7.2.) In $[Mat90]$ and $[JR]$, it was conjectured that for $p > q > 0$, $p > 3$, if we write $p/q$ as a continued fraction $[n_0, n_1, \ldots]$, then the complexity $c(L(p,q))$ is equal to $\sum n_i - 3$. It specializes to the following:

Conjecture 1.13 ($[Mat90], [JR]$). For $n > 3$, $c(L(n,1)) = n - 3$.

In $[JR]$, Jaco and Rubinstein show that $c(L(n,1)) \leq n - 3$ for general $n$. In $[JRT09]$, Jaco, Rubinstein, and Tillman prove Conjecture 1.13 for even $n$. The case of odd $n$ is still open.

We consider the 3-manifold $M(K,n)$ obtained by $n$-surgery on a knot $K$ in $S^3$ ($n \in \mathbb{Z}$), as a generalization of the lens space $L(n,1)$. Recall that we say $f(n) \in \Theta(g(n))$ if the asymptotic growth of $f(n)$ and $g(n)$ are identical, that is, there exist $C_1, C_2 > 0$ such that $C_1|g(n)| \leq |f(n)| \leq C_2|g(n)|$ for all sufficiently large $n$. (This is different from $f \in O(g(n))$, which requires the second inequality only.) The following result tells us that the complexity of $M(K,n)$ is always linear asymptotically.

Theorem 1.14. For any knot $K$ in $S^3$, $c(M(K,n)) \in \Theta(n)$.

The proof of Theorem 1.14 employs the Cheeger-Gromov invariants using Corollary 1.11. In fact, we give an explicit linear lower bound for $c(M(K,n))$; see Theorem 1.22 for more details. Applying it to the unknot, we immediately obtain the following corollary, which determines the asymptotic growth of the complexity of $L(n,1)$.

Corollary 1.15. $c(L(n,1)) \in \Theta(n)$. In fact, for each $n > 3$,

$$\frac{1}{627419520} \cdot (n - 3) \leq c(L(n,1)) \leq n - 3.$$  

This result supports Conjecture 1.13 by telling us that it is asymptotically true.

More applications of our results to the complexity of 3-manifolds will appear in a subsequent paper.

1.4. Efficient 4-dimensional bordisms over a group

One of the key ingredients of the proofs of Theorems 1.8 and 1.9 is a new result on the existence of an efficient 4-dimensional bordism over a group. More precisely, we address the following problem, which looks interesting on its own.

We consider manifolds over a group $G$, namely manifolds endowed with a map into $BG$, the classifying space of $G$. As usual, we say that $W$ is a bordism over $G$ between $M$ and $N$ if $\partial W = M \sqcup -N$ as manifolds over $G$. 
**Question 1.16.** Given a 3-manifold \( M \) over \( G \), how efficiently can \( M \) be bordant to a 3-manifold which is over \( G \) via a constant map?

To define the efficiency of a bordism rigorously, we consider the following notion of complexity of a (co)bordism, which is most natural for the study of signature invariants.

**Definition 1.17.** The 2-handle complexity of a 4-dimensional smooth/PL (co)bordism is the minimal number of 2-handles in a handle decomposition of \( W \).

Although Definition 1.17 (as well as Question 1.16) generalizes to higher dimensions in an obvious way, in this paper we focus on the low dimensional case only.

It is a standard fact that any \( L^2 \)-signature of a 4-manifold (in particular the ordinary signature) is not greater that the 2-handle complexity.

Suppose \( M \) is a triangulated 3-manifold endowed with a cellular map \( \phi : M \to BG \), and \( \zeta_M \in C_3(M) \) is the sum of the oriented 3-simplices representing the fundamental class. Then the Atiyah-Hirzebruch bordism spectral sequence tells us that the existence of a bordism \( W \) from \( M \) to another 3-manifold which is over \( G \) via a constant map is equivalent to the existence of a chain level analog: such \( W \) exists if and only if there exists a 4-chain \( u \in C_4(BG) \) satisfying \( \partial u = \phi_\#(\zeta_M) \).

For the reader’s convenience we discuss details as Lemma 3.2 in Section 3.1.

Our result (Theorem 3.9 stated below) concerning Question 1.16 is essentially that if the chain level analog \( u \in C_4(BG) \) of a desired \( W \exists \) for \((M, \phi)\), then there exists a corresponding bordism \( W \) whose 2-handle complexity is controlled linearly in the “size” of \( u \) and \( M \).

To measure the size of a chain, we define an algebraic notion of diameter as follows:

**Definition 1.18.** Suppose \( C_* \) is a based chain complex over \( \mathbb{Z} \), and \( \{e^k_\alpha\} \) is the given basis of \( C_k \). The diameter \( d(u) \) of a \( k \)-chain \( u = \sum_n n_\alpha e^k_\alpha \in C_k \) is defined to be the \( L^1 \)-norm \( d(u) = \sum |n_\alpha| \).

Note that the number of tetrahedra in a triangulation of a closed 3-manifold \( M \) is equal to the diameter of the chain \( \zeta_M \in C_3(M) \) representing the fundamental class.

In order to use the notion of the diameter for a chain in \( BG \) (particularly in Theorem 3.9 stated below), we need to fix a CW structure of \( BG \). It is known that we can obtain a \( K(G,1) \) space \( BG \) as the geometric realization of the simplicial classifying space of \( G \) (i.e., the nerve) which is a simplicial set. Due to Milnor [Mi57], this gives us an explicit CW structure for \( BG \). In addition, Milnor's geometric realization tells us that each \( n \)-cell of \( BG \) is naturally identified with the standard \( n \)-simplex. Another useful fact is that any map of a simplicial complex into \( BG \) is homotopic to a cellular map which, roughly speaking, sends simplices to simplices affinely; we call such a map simplicial-cellular. We give precise definitions and provide more details in Section 3.2 and in the appendix (in particular see Definition 3.6).

Now we can state our main result about Question 1.16:

**A special case of Theorem 3.9.** Suppose \( M \) is a triangulated closed 3-manifold with \( d(\zeta_M) \) tetrahedra, and \( M \) is over \( G \) via a simplicial-cellular map \( \phi : M \to BG \). If there is a 4-chain \( u \in C_4(BG) \) satisfying \( \partial u = \phi_\#(\zeta_M) \), then there exists a smooth bordism \( W \), between \( M \) and a 3-manifold which is over \( G \) via a constant map, whose 2-handle complexity is at most \( 195 \cdot d(\zeta_M) + 975 \cdot d(u) \).

Our proof provides a geometric construction of a desired bordism \( W \) using transversality and surgery arguments over \( G \). It may be viewed as a “geometric realization” of the algebraic idea of the Atiyah-Hirzebruch bordism spectral sequence constructed from the
exact couple arising from skeleta. To control the 2-handle complexity of \( W \) carefully, we carry out transversality and surgery arguments simplicially. Details can be found in Section 3.

We also show that the linear 2-handle complexity in (the special case of) Theorem 3.9 is asymptotically best possible. To state it, we formally define “the best possible 2-handle complexity” as a function in \( k := d(\zeta_M) + d(u) \) as follows:

**Definition 7.9.** Let \( M(k) \) be the collection of pairs \( (M, \phi) \) of a closed triangulated 3-manifold \( M \) and a simplicial-cellular map \( \phi: M \to \Omega(G) \) admitting a 4-chain \( u \in C_4(\Omega(G)) \) such that \( \partial u = \phi_\#(\zeta_M) \) and \( k = d(\zeta_M) + d(u) \). For a given \( (M, \phi) \), let \( B(M, \phi) \) be the collection of bordisms \( W \) over \( G \) between \( M \) and another 3-manifold which is over \( G \) via a constant map. Define

\[
B^{2h}(k) := \sup_{(M, \phi) \in M(k)} \min_{W \in B(M, \phi)} \{ \text{2-handle complexity of } W \}.
\]

In other words, \( B^{2h}(k) \) is the optimal (smallest) value for which the following holds: for any \( (M, \phi) \) in \( M(k) \) there is a desired bordism \( W \) with 2-handle complexity not greater than \( B^{2h}(k) \).

**Theorem 7.10.** \( B^{2h}(k) \in O(k) \cap \Omega(k) \). In fact,

\[
\frac{1}{107712} \leq \limsup_{k \to \infty} \frac{B^{2h}(k)}{k} \leq 975.
\]

Our linear optimal bound of the 2-handle complexity in Theorem 3.9 may be compared with a result of Costantino and Thurston [CT08] that a closed 3-manifold (which is not over a group) of complexity \( n \) bounds a 4-manifold whose complexity is bounded by \( O(n^2) \).

Theorem 3.9 plays an essential role in the proofs of the explicit estimates of the Cheeger-Gromov invariants of a given 3-manifold \( M \) by using bordism \( W \) obtained by applying Theorem 3.9 and by controlling the 2-handle complexity of \( W \) efficiently, we obtain the explicit universal bounds. For this purpose, we need a chain level analog \( u \) of \( W \) required in Theorem 3.9 and more importantly, we need to control the diameter of \( u \). We do this by applying a general algebraic idea introduced in the next subsection.

### 1.5. Controlled chain homotopy

The second key ingredient of the proofs of Theorems 1.5, 1.8 and 1.9 is a method to estimate of the size of certain chain homotopies, which is best described using a notion of controlled chain homotopy.

Controlled chain homotopy seems to be an interesting algebraic notion on its own, which may be compared with the topological notion of controlled homotopy. We begin by introducing the basic definition. Recall that the diameter \( d(u) \) of a chain \( u \) is defined to be its \( L^1 \)-norm (see Definition 1.18). As a convention, we assume that a chain complex \( C_* \) is positive, namely \( C_i = 0 \) for \( i < 0 \).

**Definition 1.19.** Suppose \( C_* \) and \( D_* \) are based chain complexes, and \( P: C_* \to D_{*+1} \) is a chain homotopy. We define the diameter function \( d_P: \mathbb{Z} \to \mathbb{Z}_{\geq 0} \cup \{ \infty \} \) of \( P \) by

\[
d_P(k) := \max \{ d(P(c)) \mid c \in C_i \text{ is a basis element}, i \leq k \}.
\]

For a partial chain homotopy \( P \) defined on \( C_i \) for \( i \leq N \) only, we define \( d_P(k) \) for \( k \leq N \) exactly in the same way.

Let \( \delta \) be a function from the domain of \( d_P \) to \( \mathbb{Z}_{\geq 0} \). We say that \( P \) is a \( \delta \)-controlled (partial) chain homotopy if \( d_P(k) \leq \delta(k) \) for each \( k \) in the domain of \( d_P \).
Note that $d_P(k)$ may be infinity in general. If $P$ is a (partial) chain homotopy defined on a finitely generated positive chain complex, then $d_P(k)$ is finite whenever defined.

**Definition 1.20.** Suppose $S = \{P_A : C^A_k \to D^A_{k+1}\}_{A \in I}$ is a collection of chain homotopies, or a collection of partial chain homotopies defined in dimensions $\leq n$ for some fixed $n$. We say that $S$ is uniformly controlled by $\delta$ if each $P_A$ is a $\delta$-controlled (partial) chain homotopy. The function $\delta$ is called a control function for $S$.

Our focus is to understand how various families of chain homotopies can be uniformly controlled. A few additional words might make it clearer. In many cases the conclusion of a theorem on chain complexes can be understood as the existence of a certain chain homotopy, and in addition, such a theorem usually holds for a collection of objects, so that it indeed gives a family of chain homotopies indexed by the objects. For example, the classical Eilenberg-Zilber theorem says that $C_*(X \times Y)$ and $C_*(X) \otimes C_*(Y)$ are chain homotopy equivalent, that is, for every $(X, Y)$ there are chain homotopies which tell us that the chain complexes are chain homotopy equivalences. Are these chain homotopies indexed by $(X, Y)$ uniformly controlled?

In general, we consider the following meta-question:

**Question 1.21.** Pick a theorem about chain complexes or their homology. In case of based chain complexes or their homology, can the theorem be understood in terms of uniformly controlled chain homotopies? If so, find (an estimate of) a control function.

In this paper, we observe several interesting cases for which a family of uniformly controlled chain homotopies exists, and we analyze the control functions in detail, aiming to applications to our study of the Cheeger-Gromov bound.

Our first theorem concerns the acyclic model theorem of Eilenberg and MacLane, which gives a family of functorial chain homotopies. As a fundamental observation, we show that if we use finitely many models in each dimension, then there is a single control function $\delta$ such that all the resulting functorial chain homotopies obtained by an acyclic model argument are uniformly controlled by $\delta$. It holds even when infinitely generated chain complexes are involved (e.g., the chain complex of an infinite CW complex). This result, which we call a controlled acyclic model theorem, is stated as Theorem 4.3. We discuss more details in Section 4.1.

As an application, we apply the controlled acyclic model theorem to products. In Section 4.2 we consider simplicial sets and the Moore complexes of the associated freely generated simplicial abelian groups, as a general setup for products and based chain complexes. We present a controlled Eilenberg-Zilber theorem, which essentially says that the chain homotopy equivalence between the chain complex of a product and the tensor products of chain complexes can be understood in terms of uniformly controlled functorial chain homotopies. See Theorem 4.4 for more details.

We also consider the context of group homology. Recall that conjugation on a group induces the identity on the homology with integral coefficients. Generalizing this quantitatively in terms of chain homotopies, we show that for each pair $(G, g)$ of a group $G$ and an element $g \in G$, there is a $\delta$-controlled chain homotopy between the chain maps on the bar complex (with integral coefficients) induced by the identity and the conjugation by $g$ on $G$, where $\delta$ is the function defined by $\delta(k) = k + 1$, independent of $(G, g)$. For a precise statement and related discussions, see Theorem 4.5 and Section 4.3.

We give another uniformly controlled chain homotopy result, concerning the result of Baumsagl, Dyer, and Heller [BDH90] which was already mentioned as a key ingredient of our topological proof of the existence of the Cheeger-Gromov bound (Theorem 1.3): there
is a functorial embedding, say \( i_G : G \hookrightarrow A(G) \), of a group \( G \) into an acyclic group \( A(G) \) for each group \( G \). From the viewpoint of controlled chain homotopy, the following natural question arises: for each \( G \), is there a chain homotopy between the chain maps induced by the identity \( \text{id}_{A(G)} \) and the trivial endomorphism of \( A(G) \), which forms a uniformly controlled family?

We give a partial answer. In [BDH80], for each \( n \geq 1 \), they constructed a functorial embedding that we denote by \( i^n_G : G \to \mathcal{A}^n(G) \), which induces a zero map \( H_i(G; k) \to H_i(\mathcal{A}^n(G); k) \) for \( 1 \leq i \leq n \) and any field \( k \). (See Definition 5.1 for a precise description of \( \mathcal{A}^n(G) \).) This may be viewed as an approximation of a functorial embedding into acyclic groups up to dimension \( n \); in fact it turns out that \( \lim \mathcal{A}^n(G) \) is acyclic and \( G \) embeds into it functorially. The following result is a controlled chain homotopy generalization of the homological property of \( i^n_G \).

**Theorem 5.2.** For each \( n \), there is a family \( \{ \Phi^n_G \mid G \text{ is a group} \} \) of partial chain homotopies \( \Phi^n_G \) defined in dimension \( \leq n \) between the chain maps induced by the trivial map \( e : G \to \mathcal{A}^n(G) \) and the embedding \( i^n_G : G \to \mathcal{A}^n(G) \), which is uniformly controlled by a function \( \delta_{BDH} \). For \( k \leq 4 \), the value of \( \delta_{BDH}(k) \) is as follows.

Our proof of Theorem 5.2 consists of a careful construction of the chain homotopy \( \Phi^n_G \) and its diameter estimate, using the above results on the acyclic model theorem and conjugation. We provide more detailed discussions and proofs in Section 5.

We remark that Theorem 5.2 for \( n = 3 \) (together with \( \delta_{BDH}(3) = 186 \)) is sufficient for our proofs of the Cheeger-Gromov bound estimates for 3-manifolds. See Section 6 for more details.

**Organization of the paper.** In Section 2 we review the \( L^2 \)-signature approach to the Cheeger-Gromov \( \rho \)-invariant and give a topological proof of Theorem 1.3. In Section 3 we give a construction of 4-dimensional bordisms and estimate the 2-handle complexity to prove Theorem 1.17. In Section 4 we develop basic theory of controlled chain homotopy, including a controlled acyclic model theorem. In Section 5 we present a chain level approach to Baumslag-Dyer-Heller’s result and then prove Theorem 5.2. In Section 6 we obtain explicit estimates for the Cheeger-Gromov universal bound by proving Theorems 1.18 and 1.19. In Section 7 we discuss the application to the complexity of 3-manifolds, and prove that our linear Cheeger-Gromov bounds and geometric construction of efficient bordisms are asymptotically optimal. In the appendix, we discuss basic definitions and facts on simplicial sets and simplicial classifying spaces which we use in this paper, for the reader’s convenience.

### 2. Existence of universal bounds

In this section we give a topological proof of the existence of a universal bound for the Cheeger-Gromov invariant \( \rho^{(2)}(M, \phi) \).
2.1. A topological definition of the Cheeger-Gromov $\rho$-invariant

We begin by recalling a known topological definition of $\rho^{(2)}(M, \phi)$. We follow the approach introduced by Chang and Weinberger [CW03]; see also Harvey’s work [Har08]. Suppose $M$ is a closed topological $(4k - 1)$-manifold, and $\phi: \pi_1(M) \to G$ is a homomorphism. When $X$ is not path connected, as a convention, we denote by $\pi_1(X)$ the free product of the fundamental groups of the path components of $X$. Suppose $W$ is a $4k$-manifold with $\partial W = rM$, $r$ disjoint copies of $M$. Suppose there are a monomorphism $G \hookrightarrow \Gamma$ and a homomorphism $\pi_1(W) \to \Gamma$ which make the following diagram commute:

\[
\begin{array}{ccc}
\prod_{i=1}^r \pi_1(M) & \xrightarrow{\pi_1(rM)} & G \\
\downarrow \downarrow & & \downarrow \downarrow \\
\pi_1(W) & \xrightarrow{\phi} & \Gamma
\end{array}
\]

For a (discrete) group $\Gamma$, the group von Neumann algebra $\mathcal{N} \Gamma$ is defined as an algebra over $\mathbb{C}$ with involution. Lück’s book [Lück02] is a useful general reference on $\mathcal{N} \Gamma$; see also his paper [Lück98]. In this paper we need the following known facts on $\mathcal{N} \Gamma$: (i) $C \Gamma \subset \mathcal{N} \Gamma$ as a subalgebra. Consequently, in our case, $\mathcal{N} \Gamma$ is a local coefficient system over $W$ via $C[\pi_1(W)] \to C \Gamma \subset \mathcal{N} \Gamma$. The homology $H_*(W; \mathcal{N} \Gamma)$ is defined as usual, and by Poincaré duality, the intersection form $\lambda: H_{2k}(W; \mathcal{N} \Gamma) \times H_{2k}(W; \mathcal{N} \Gamma) \to \mathcal{N} \Gamma$ is defined. (ii) $\mathcal{N} \Gamma$ is semihereditary, that is, any finitely generated submodule of a finitely generated projective module over $\mathcal{N} \Gamma$ is projective; consequently, in our case, $H_{2k}(W; \mathcal{N} \Gamma)$ is a finitely generated module over $\mathcal{N} \Gamma$. (iii) For any hermitian form over a finitely generated $\mathcal{N} \Gamma$-module, there is a spectral decomposition; in our case, for the intersection form $\lambda$, we obtain an orthogonal direct sum decomposition

\[
H_{2k}(W; \mathcal{N} \Gamma) = V_+ \oplus V_- \oplus V_0
\]

such that $\lambda$ is positive definite, negative definite, and zero on $V_+, V_-$, and $V_0$ respectively. (iv) There is a dimension function

\[
\dim_{(2)}: \{\text{finitely generated } \mathcal{N} \Gamma\text{-modules}\} \to \mathbb{R}_{\geq 0}
\]

which is additive for short exact sequences and satisfies $\dim_{(2)}(\mathcal{N} \Gamma) = 1$.

The $L^2$-signature of $W$ over $\Gamma$ is defined to be

\[\text{sign}_{(2)} W = \dim_{(2)} V_+ - \dim_{(2)} V_- .\]

Now the $L^2$ $\rho$-invariant of $(M, \phi)$ is defined to be the signature defect

\[\rho^{(2)}(M, \phi) = \frac{1}{r} \left( \text{sign}_{(2)} W - \text{sign} W \right)\]

where $\text{sign} W$ denotes the ordinary signature of $W$.

It is known that this topological definition of $\rho^{(2)}(M, \phi)$ is equivalent to the definition of Cheeger and Gromov given in [CG85] in terms of $\eta$-invariants. The proof depends on the $L^2$-index theorem for manifolds with boundary [CG85, Ram93] and the fact that various known definitions of $L^2$-signatures are equivalent [LS03]. We remark that Cochran and Teichner present an excellent introduction to the analytic definition of $\rho(M, \phi)$ in [CT07, Section 2].
Although the $L^2$-signature defect definition involves the bounding manifold $W$ (and the enlargement $\Gamma$ of the given $G$), it is known that a topological argument using bordism theory shows that such a $W$ always exists and that $\rho_{2}(M, \phi)$ in (2.3) is independent of the choice of $W$, without appealing to analytic index theory. To the knowledge of the author, this method for the $L^2$-case first appeared in [CW03]. Since it is closely related to our techniques for the universal bound of the $\rho$-invariants that will be discussed in later sections, we give a proof below, without claiming any credit.

For the existence of $W$, we use a result of Kan and Thurston [KT76] that a group $G$ embeds into an acyclic group, say $\Gamma$. Denote by $\Omega^\text{STOP}_n$ and $\Omega^\text{STOP}_n(X)$ the oriented topological cobordism and bordism groups. By the foundational work of Kirby-Siebenmann [KS77] and Freedman-Quinn [FQ90], $\Omega^\text{STOP}$-ented topological cobordism and bordism groups. By the foundatio nal work of Kirby-

sequence Ω

(\Gamma$).

For the independence of the choice of $W$, suppose the diagram (2.1) is also satisfied for $(W', r', \Gamma')$ in place of $(W, r, \Gamma)$. By $L^2$-induction (see, e.g., [CG85 Equation (2.3)], [Liu02 p. 253], [COT03 Proposition 5.13]), $\text{sign}^{(2)}$ is left unchanged when $\Gamma$ is replaced by another group containing $\Gamma$ as a subgroup. Thus we may assume that $\Gamma = \Gamma'$ by replacing $\Gamma$ and $\Gamma'$ with the amalgamated product of them over $G$, and furthermore we may assume that $\Gamma$ is acyclic using Kan-Thurston. Let $V = r'W \cup_{r'M} -rW'$. Then $V$ is a closed 4

k

manifold over $\Gamma$. Since $\Gamma$ is acyclic, $\Omega^\text{STOP}_{4k}(\Gamma) \simeq \Omega^\text{STOP}_{4k}(B\Gamma)$, and therefore $V$ is bordant to another $V'$ which is over $B\Gamma$ via a constant map. We have $\text{sign}^{(2)}(V') = \text{sign} V'$. Using Novikov additivity and that $\text{sign}^{(2)}$ and sign are bordism invariants, we obtai

\[
\frac{1}{r'} (\text{sign}_1^{(2)} W - \text{sign} W) - \frac{1}{r'} (\text{sign}_1^{(2)} W' - \text{sign} W') = \frac{1}{rr'} (\text{sign}_1^{(2)} V - \text{sign} V) = \frac{1}{rr'} (\text{sign}_1^{(2)} V' - \text{sign} V') = 0.
\]

We remark that we may assume the codomain $G$ of $\phi: \pi_1(M) \to G$ is countable. In fact, by $L^2$-induction, $\rho_2(M, \phi)$ is left unchanged when $G$ is replaced by the countable group $\phi(\pi_1(M))$.

2.2. Existence of a universal bound

In this subsection we give a new proof of the existence of the Cheeger-Gromov universal bound, which applies directly to topological manifolds. Recall Theorem 1.3 from the introduction: for any closed topological $(4k - 1)$-manifold $M$, there is a constant $C_M$ such that $|\rho_2(M, \phi)| \leq C_M$ for any homomorphism $\phi$ of $\pi_1(M)$.

In proving this using the topological definition of the Cheeger-Gromov invariants in Section 2.1, it is crucial to understand the “size” of the bounding 4

k

manifold $W$, since $\rho_2(M, \phi)$ is given by the $L^2$-signature defect of $W$ as in (2.3). The key difficulty which is well known to experts is that the 4

k

manifold $W$ in Section 2.1 depends on $\phi: \pi_1(M) \to G$ in general, since $W$ is obtained by appealing to bordism theory over an acyclic group $\Gamma$, which depends on the group $G$. 

We resolve this difficulty by employing the following functorial embedding of groups into acyclic groups, which was given by Baumslag, Dyer, and Heller.

**Theorem 2.1** (Baumslag-Dyer-Heller [BDH80, Theorem 5.5]). There exist a functor $A: \mathbf{Gp} \rightarrow \mathbf{Gp}$ on the category $\mathbf{Gp}$ of groups and a natural transformation $\iota: \text{id}_\mathbf{Gp} \rightarrow A$ such that $A(G)$ is acyclic and $\iota_G: G \rightarrow A(G)$ is injective for any group $G$.

We remark that $A(G)$ given in [BDH80] has the same cardinality as $G$ if $G$ is infinite, and is generated by $(n+5)$ elements if $G$ is generated by $n$ elements.

**Proof of Theorem 1.3.** Consider $\iota\pi_1(M): \pi_1(M) \rightarrow A(\pi_1(M))$ given by Theorem 2.1. Since $A(\pi_1(M))$ is acyclic, there is a $4k$-manifold $W$ bounded by $rM$ over $A(\pi_1(M))$ for some $r > 0$, by the bordism argument in Section 2.1. Suppose $\phi: \pi_1(M) \rightarrow G$ is arbitrarily given.

Let $\Gamma := A(G)$. Then we have the following commutative diagram, by the functoriality of $A$:

\[
\begin{array}{cccccc}
\prod \pi_1(M) & \xrightarrow{\Pi \phi} & G & \xrightarrow{\iota_G} & A(G) = \Gamma \\
\downarrow \iota_* & & & & \downarrow \phi \\
\pi_1(W) & \xrightarrow{A(\phi)} & A(\pi_1(M)) & \xrightarrow{A(\iota)} & A(G) = \Gamma
\end{array}
\]

From this it follows that we can define $\rho^{(2)}(M, \phi)$ as the $L^2$-signature defect of $W$ over $\Gamma$, as in (2.3). Note that our $W$ is now independent of the choice of $\phi$.

Recall that $W$ has the homotopy type of a finite CW complex. Let $C_*(W; N\Gamma)$ be the cellular chain complex defined using this CW structure. We have $C_{2k}(W; N\Gamma) \cong (N\Gamma)^N$ where $N$ is the number of the $2k$-cells. By the additivity of the $L^2$-dimension under short exact sequences, we have

\[
|\text{sign}^{(2)}_W| \leq \text{dim}^{(2)}_F V_+ + \text{dim}^{(2)}_F V_- \\
\leq \text{dim}^{(2)}_F H_{2k}(W; N\Gamma) \leq \text{dim}^{(2)}_F C_{2k}(W; N\Gamma) = N.
\]

A similar argument shows that $|\text{sign}W| \leq N$. By (2.3), it follows that $|\rho^{(2)}(M, \phi)| \leq 2N$. This completes the proof, since $W$, and consequently $N$, are independent of the choice of $\phi$ and $G$.

3. **Construction of bordisms and 2-handle complexity**

In this section, we introduce a general geometric construction which relates chain level algebraic data to a 4-dimensional bordism of a given 3-manifold. It may be viewed as a geometric incarnation of the Atiyah-Hirzebruch bordism spectral sequence. Furthermore, we give a more thorough analysis to obtain an explicit relationship between the complexity of the given algebraic data and the number of the 2-handles of an associated 4-dimensional bordism.

The results in this section will be used to reduce the problem of finding a universal bound for the $\rho$-invariants to a study of algebraic topological chain level information.
3.1. Geometric construction of bordisms

We begin with a straightforward observation on the Atiyah-Hirzebruch bordism spectral sequence, which is stated as Lemma 3.2 below. In this and following sections, we consider the category of spaces $X$ endowed with a map $\phi: X \to K$, where $K$ is a fixed connected CW complex. We say that $X$ is over $K$. If $K = B\Gamma$ for a group $\Gamma$, we say that $X$ is over $\Gamma$. In this case we often view $\phi: X \to K$ as $\phi: \pi_1(X) \to \Gamma$ and vice versa.

We say that $X$ is trivially over $K$ if $X$ is endowed with a constant map into $K$.

Definition 3.1. A bordism $W$ with $\partial W = M \sqcup -N$ over $K$ is called a bordism between $M$ and a trivial end if $N$ is trivially over $K$.

Lemma 3.2. For a closed $3$-manifold $M$ endowed with $\phi: M \to K$, the following are equivalent.

1. $M$ bounds a smooth $4$-manifold $V$ over $K$.
2. There is a smooth bordism $W$ over $K$ between $M$ and a trivial end.
3. The image $\phi_*[M]$ of the fundamental class $[M] \in H_3(M)$ is zero in $H_3(K)$.

Proof. (1) implies (2) obviously. (2) implies (1) since $N := \partial W \setminus M$ bounds a $4$-manifold which can be used to cap off $W$. From the Atiyah-Hirzebruch spectral sequence

$$E^{2}_{p,q} = H_p(K) \otimes \Omega^SO_q \Rightarrow \Omega^SO_n(K)$$

and from that $\Omega^SO_0 = \mathbb{Z}$, $\Omega^SO_1 = \Omega^SO_2 = \Omega^SO_3 = 0$, it follows that $\Omega^SO_3(K) \cong H_3(K)$ under the isomorphism sending the bordism class of $\phi: M \to K$ to $\phi_*[M] \in H_3(K)$. This shows that (1) is equivalent to (3).

Remark 3.3. If $(M, \phi)$ is as in Lemma 3.2 and $K = B\Gamma$, then $\rho(2)(M, \phi)$ can be defined as the $L^2$-signature defect of the bordism $W$ in Lemma 3.2 (2), as well as $V$ in Lemma 3.2 (1). For, if $N$ is over $\Gamma$ via $\psi$ and $\partial W = M \sqcup -N$ over $\Gamma$, then $\rho(2)(M, \phi) - \rho(2)(N, \psi)$ is the $L^2$-signature defect of $W$ by (2), and since the $L^2$-signature over a trivial map is equal to the ordinary signature, we have $\rho(2)(N, \psi) = 0$ if $\psi$ is trivial.

Suppose $M$ is a closed $3$-manifold equipped with a CW structure, whose $3$-cells are oriented so that the sum $\zeta_M$ of the $n$-cells is a cycle representing the fundamental class $[M] \in H_3(M)$. We may assume that $\phi: M \to K$ is cellular by appealing to the cellular approximation theorem. Let $\phi_u$ be the chain map on the cellular chain complex $C_*(-)$ induced by $\phi$. Then we can restate Lemma 3.2 (3) as follows:

Addendum to Lemma 3.2 (3) $\phi_u(\zeta_M) = \partial u$ for some $4$-chain $u$ in $C_4(K)$.

The goal of this section is to discuss a more explicit relationship of the $4$-dimensional bordism $W$ in Lemma 3.2 (2) and the $4$-chain $u$ in Lemma 3.2 (3)'.

As an easier direction, if $W$ is a bordism between $M$ and a trivial end $N$, then for the sum $\zeta_W$ of oriented $4$-cells of $W$ which represent the fundamental class of $(W, \partial W)$, we have $\partial W = \zeta_M - \zeta_N$. Since the image of $\zeta_N$ in $C_4(K)$ is zero, the image $u \in C_4(K)$ of $\zeta_W$ satisfies $\partial u = \phi_u(\zeta_M)$.

For the converse, for a given $4$-chain $u \in C_4(K)$ satisfying Lemma 3.2 (3)', we will present a construction of a bordism $W$ between $M$ and a trivial end. The rest of this subsection is devoted to this. This will tell us how the Atiyah-Hirzebruch spectral sequence is reinterpreted as a geometric construction, and provide us the foundational idea of the more sophisticated analysis accomplished in Section 3.3.
**Preparation and strategy.** As above, suppose a given closed 3-manifold $M$ has a fixed CW complex structure, and $\phi: M \to K$ is cellular. Suppose $\phi_{\#}(\zeta_M) = \partial u$ for some $u \in C_4(K)$.

Our construction of $W$ is based on the following observation. Let $K^{(i)}$ be the $i$-skeleton of $K$. By Atiyah-Hirzebruch, $\Omega^3_{SO}(G)$ is filtered by

$$\Omega^3_{SO}(G) = J_3 \supset J_2 \supset J_1 \supset J_0 \supset J_{-1} = 0$$

where $J_i = \text{Im} \{\Omega^3_{SO}(K^{(i)}) \to \Omega^3_{SO}(K)\}$, and as in the proof of Lemma 3.2 we have

$$(3.1) \quad J_i/J_{i-1} \cong E_i^{SO} \cong E_i^{2,3-i} = H_1(K) \otimes \Omega^3_{SO} = \begin{cases} H_1(K) & \text{if } i = 3 \\ 0 & \text{if } i = 0, 1, 2. \end{cases}$$

Let $M_3 := M$. Obviously $\phi$ maps $M_3$ into $K^{(3)}$. For $i = 3$, (3.1) tells us that the existence of $u$ implies that the bordism class of $(M_3, \phi)$ in $\Omega^3_{SO}(K^{(3)})$ lies in the image of $\Omega^3_{SO}(K^{(2)})$, that is, there is a bordism $W_3$ over $K$ between $M_3$ and another 3-manifold, say $M_2$, such that $M_2$ maps to $K^{(2)}$. Similarly, for $i = 2$ and then for $i = 1$, (3.1) tells us that $\Omega^3_{SO} = 0$ implies that $M_i$ over $K^{(i)}$ admits a bordism $W_i$ over $K$ to another 3-manifold $M_{i-1}$ that maps into $K^{(i-1)}$.

Once we have the bordisms $W_i$ for $i = 3, 2, 1$, by concatenating them, we obtain a bordism $W$ between the given $M$ and the 3-manifold $N := M_0$. Since $K$ is a connected CW complex, $N \to K^{(0)}$ is homotopic to a constant map. By altering the map $W \to K$ on a collar neighborhood of $N$ using the homotopy, we may assume that $N$ is over $K$ via a constant map. This gives a desired bordism $W$ between the given $M$ and a trivial end $N$.

In Steps 1, 2, and 3 below, we present how to actually construct $W_3$, $W_2$, and $W_1$, using the given $u$ and the facts $\Omega^3_{SO} = 0$, respectively.

**Step 1: Reduction to the 2-skeleton $K^{(2)}$.** We will construct $W_3$ using the given 4-chain $u$. Denote the characteristic map of a 4-cell $e^4_\alpha$ of $K$ by $\phi_{\alpha}: D^4_\alpha \to K^{(4)}$ where $D^4_\alpha$ is a 4-disk. We may assume that the center of each 3-cell of $K$ is a regular value of $\phi: M \to K^{(3)}$ and a regular value of each attaching map $\phi_{\alpha}|_{\partial D^4_\alpha}: \partial D^4_\alpha \to K^{(3)}$. Write the 4-chain $u$ as $u = -\sum_\alpha n_\alpha e^4_\alpha$, and consider the 4-manifold $X = M \times [0, 1] \cup \bigsqcup_\alpha n_\alpha D^4_\alpha$. View $X$ as a bordism over $K$ between $M \times 0$ and $M' := \partial X \times M \times 0$, via the map $X \to K$ induced by $\phi$ composed with the projection $M \times [0, 1] \to M$ and the maps $\phi_{\alpha}$. Let $\psi: M' \to K$ be its restriction. The relation $\phi_{\#}(\zeta_M) = \partial u = 0$ implies that for the center $y$ of each 3-cell of $K$, the points in $\psi^{-1}(y) \in M'$ signed by the local degree are cancelled in pairs. For each cancelling pair, attach to $X$ a 1-handle joining these; the attaching 0-sphere is framed by pulling back a fixed framing at the regular value $y$, as usual. Let $W_3$ be the resulting cobordism, which is from $M = M \times 0$ to another 3-manifold, say $M_2$. The map $\psi$ induces a map $W_3 \to K^{(4)}$ which maps $M \sqcup M_2$ into $K^{(3)}$. In addition, the image of $M_2$ is disjoint to the centers of 3-cells in $K^{(3)}$. It follows that by a homotopy on a collar neighborhood, we may assume that $M_2$ is mapped into $K^{(2)}$. This completes Step 1, as summarized in the following diagram:

$$\begin{array}{cc}
M = M_3 \leftarrow W_3 \rightarrow M_2 \\
K^{(4)} \downarrow \phi \downarrow K^{(3)} \rightarrow K^{(2)}
\end{array}$$

**Step 2: Reduction to the 1-skeleton $K^{(1)}$.** For the map $\phi_2: M_2 \to K^{(2)}$ obtained above, we may assume that the center $y$ of a 2-cell of $K^{(2)}$ is a regular value. Then $\phi_2^{-1}(y)$
is a disjoint union of framed circles in $M_2$. Take $M_2 \times [0, 1]$, and attach 2-handles along the components of the framed 1-manifold $\phi_2^{-1}(y) \times 1 \subset M_2$. This gives a 4-dimensional cobordism $W_2$ from $M_2 = M_2 \times 0$ to another 3-manifold $M_1$, and $\phi_2$ extends to $W_2 \to K^{(2)}$. By the construction, the image of $M_1$ in $K^{(2)}$ is disjoint to the centers of 2-cells. Therefore by a homotopy we may assume that $W_2 \to K^{(2)}$ restricts to a map $\phi_1 : M_1 \to K^{(1)}$.

We remark that in the above argument $\Omega_1 = 0$ is used as that a circle bounds a disk so that we can attach a 2-handle along a circle.

**Step 3: Reduction to the 0-skeleton $K^{(0)}$.** For the map $\phi_1 : M_1 \to K^{(1)}$, we may assume that the center of each 1-cell of $K^{(1)}$ is a regular value of $\phi_1$. Then $S := \phi_1^{-1}(\{\text{centers of 1-cells}\})$ is a framed 2-submanifold in $M$. Since there is a union of handlebodies, say $R$, bounded by $S$, we can do “surgery” along $S$. More precisely, we obtain the trace of surgery by attaching $R \times [-1,1]$ to $M_1 \times [0,1]$ along $S \times [-1,1] = \text{normal bundle of } S$ in $M_1 \times 1$. Performing this for each 1-cell of $K^{(1)}$, we obtain a cobordism $W_1$ from $M_1 = M_1 \times 0$ to another 3-manifold $M_0$, which is endowed with an induced map $W_1 \to K^{(1)}$. Similarly to the above, since the image of $M_0$ in $K^{(1)}$ under this map is away from the centers of 1-cells, we may assume that $M_0$ is mapped into $K^{(0)}$, by a homotopy.

We remark that in the above argument $\Omega_2 = 0$ is used as that the 2-manifold $S$ bounds a 3-manifold $R$.

The following diagram summarizes the above construction:

![Diagram showing the construction](image)

**Remark 3.4.** The operation of “surgery along a surface $S$” in Step 3 above can be translated to standard handle attachments as follows. Let $g_i$ be the genus of a component $S_i$ of $S = \phi_1^{-1}(\{\text{centers of 1-cells}\})$, and $R_i$ be a handlebody bounded by $S_i$. Viewing $R_i$ as a 0-handle $D^3$ with $g_i$ 1-handles $D_{ij}^2 \times [-1,1]$ ($1 \leq j \leq g_i$) attached, and then turning it upside-down, we see that attaching $R_i \times [-1,1]$ along $S_i \times [-1,1]$ is equivalent to attaching $D_{ij}^2 \times [-1,1]^2$ along $\partial D_{ij}^2 \times [-1,1]^2$ as 2-handles, and then attaching $D^3 \times [-1,1]$ along $\partial D^3 \times [-1,1]$ as a 3-handle. It follows that the bordism $W_1$ in Step 3 above consists of $(g_1 + \cdots + g_r)$ 2-handles and $r$ 3-handles, where $r$ is the number of components of $S$. This observation will be useful in Section 3.3.

**Remark 3.5.** From Steps 1, 2, and 3 above and from Remark 3.4 we obtain a handle decomposition of the bordism $W$. However, the above construction which uses CW complexes does not give bounds on the number of handles of $W$. For instance, regarding 2-handles, if we write $s$ as the number of components of $\phi_2^{-1}(\{\text{centers of 2-cells}\})$, and if $r$ and the $g_i$ are as in Remark 3.4, then our $W$ has $s + (g_1 + \cdots + g_r)$ 2-handles. Transversality arguments do not provide any control on the number of components $s$ and $r$ and the genera $g_i$ of the pre-image; in fact, a homotopy can increase $s$, $r$, and $g_i$ arbitrarily. In order to provide an efficient control, we will use a simplicial setup and perform a more sophisticated analysis in Section 3.3.

### 3.2. Simplicial-cellular approximations of maps into classifying spaces

In this subsection, we discuss some geometric ideas that arises from elementary simplicial set theory, for readers not familiar to simplicial sets. (We present a short brief review
of basic necessary facts on simplicial sets in the appendix, for the reader’s convenience.)
These will be used in the next subsection, in order to control the 2-handle complexity of a bordism $W$.

We first formally state a generalization of simplicial complexes and simplicial maps, by extracting geometric properties of simplicial sets (and their geometric realizations) that we need.

**Definition 3.6.** Let $\Delta^n$ be the standard $n$-simplex.

1. A CW complex $X$ is a *pre-simplicial-cell complex* if each $n$-cell is endowed with a characteristic map of the form $\Delta^n \to X$. In particular, an open $n$-cell is identified with the interior of $\Delta^n$. Often we call an $n$-cell an *$n$-simplex*. Note that a simplicial complex is a pre-simplicial-cell complex in an obvious way.

2. A cellular map $X \to Y$ between pre-simplicial-cell complexes $X$ and $Y$ is called a *simplicial-cellular map* if its restriction on an open $k$-simplex of $X$ is a surjection onto an open $\ell$-simplex of $Y$ ($\ell \leq k$) which extends to an affine surjection $\Delta^k \to \Delta^\ell$ sending vertices to vertices.

3. A pre-simplicial-cell complex $X$ is a *simplicial-cell complex* if the attaching map $\partial \Delta^k \to X$ of every $k$-cell is simplicial-cellular. Here we view the simplicial complex $\partial \Delta^k$ as a pre-simplicial-cell complex.

As abuse of terminology, we do not distinguish a simplicial-cell complex from its underlying space. Similarly for simplicial and CW complexes.

We note that the composition of simplicial-cellular maps is simplicial-cellular.

As an example, a simplicial complex is a simplicial-cell complex, and a simplicial map between simplicial complexes is a simplicial-cellular map. More generally, simplicial sets give us simplicial-cell complexes. More precisely, a simplicial set has the geometric realization, which is a CW complex due to Milnor [Mil57]; in fact, his proof shows that the geometric realization is a simplicial-cell complex in the sense of Definition 3.6. See the appendix (§1) for a more detailed discussion.

The following special case will play a key role in the next subsection. It is well known that for a group $G$ a $K(G,1)$ space is obtained as the geometric realization of the simplicial classifying space, that is, the nerve of $G$ (for example see [GJ09, p. 6], [Wei94, p. 257]). From now on, we denote this $K(G,1)$ space by $BG$. By the above, $BG$ is a simplicial-cell complex. We remark that $BG$ is not necessarily a simplicial complex.

**Theorem 3.7** (Simplicial-cellular approximation of maps into $BG$). *Suppose $X$ is the geometric realization of a simplicial set. Then any map $X \to BG$ is homotopic to a simplicial-cellular map.*

In this paper, we will apply Theorem 3.7 to a simplicial complex $X$; we note that a simplicial complex gives rise to a simplicial set (by ordering the vertices).

Since the author did not find it in the literature, a proof of Theorem 3.7 is given in the appendix; see Proposition A.5.

**Remark 3.8.** Theorem 3.7 may be compared with the standard simplicial and cellular approximation theorems. The simplicial approximation respects the simplicial structure but requires a subdivision of the domain. On the other hand, the cellular approximation does not require a subdivision but does not respect simplicial structures. Theorem 3.7 respects the simplicial structures and requires no subdivision. The latter is an important feature too, since controlling the number of simplicies is essential for our purpose.
3.3. Estimating the 2-handle complexity

In this subsection we present a simplicial refinement of the transversality-and-surgery arguments used in Section 3.1, and find an upper bound of the 2-handle complexity of the resulting bordism.

We define the complexity of a triangulated 3-manifold to be the number of 3-simplices. (Note that this is different from the notion of the (simplicial) complexity of a 3-manifold.)

Recall from the introduction that the 2-handle complexity of a 4-dimensional bordism $W$ is the minimal number of 2-handles in a handle decomposition of $W$.

For a triangulated closed 3-manifold $M$, let $\zeta_M$ be the sum of oriented 3-simplices of $M$ which represents the fundamental class, as we did for a CW complex structure. Recall that the diameter $d(\zeta_M)$ is equal to the complexity of the triangulation.

The main result of this subsection is the following.

**Theorem 3.9.** Suppose $M$ is a closed triangulated 3-manifold with complexity $d(\zeta_M)$. Suppose $M$ is over a simplicial-cellular complex $K$ via a simplicial-cellular map $\phi: M \to K$. If there is a 4-chain $u \in C_4(K)$ satisfying $\partial u = \phi_\#(\zeta_M)$, then there exists a smooth bordism $W$ between $M$ and a trivial end whose 2-handle complexity is at most $195 \cdot d(\zeta_M) + 975 \cdot d(u)$.

We remark that when $K = 
\square$, any map $\phi: M \to K$ may be assumed to be a simplicial-cellular map up to homotopy, by Theorem 3.7.

Recall that in Section 3.1 we constructed a bordism $W$ between $M$ and a trivial end by stacking bordisms $W_3$, $W_2$, and $W_1$ such that $\partial W_1 = M_i \cup -M_{i-1}$ over $K$, where $M_3 := M$ is the given 3-manifold, and $M_i$ is over $K$ via a map $\phi_i: M_i \to K^{(i)}$ into the $i$-skeleton for each $i$. The main strategy of our proof of Theorem 3.9 is to refine the construction of the $W_i$ carefully to control the number of 2-handles. For this purpose, we will triangulate $M_i$ and make $\phi_i$ simplicial-cellular. For the initial case, $M_3 = M$ is triangulated and $\phi_3 = \phi$ is simplicial-cellular by the hypothesis of Theorem 3.9. Arguments for $W_i$ and $M_{i-1}$ for $i = 3, 2, 1$ are given as the three propositions below.

**Proposition 3.10 (Step 1: Reduction to $K^{(2)}$ and complexity estimate).** Suppose $M$, $\phi$, $u$ are as in Theorem 3.9. Then there is a triangulated 3-manifold $M_2$ with complexity at most $n_2 := 18 \cdot d(\zeta_M) + 90 \cdot d(u)$, which is over $K$ via a simplicial-cellular map $\phi_2: M_2 \to K^{(2)}$, and there is a bordism $W_2$ over $K$ between $M$ and $M_2$ which has no 2-handles.

**Proof.** Following Step 1 in Section 3.1 we write $u = \sum n_0 \sigma_0^4$, where the $\sigma_0^4$ are 4-simplices of $K$ with attaching maps $\phi_0: \partial \Delta_0^4 \to K^{(1)}$. Here $\Delta_0^4$ is a standard 4-simplex. Let $X := (M \times [0,1]) \cup (\bigsqcup n_0 \Delta_0^4)$. The 4-manifold $X$ is a bordism over $K$ between $M = M \times 0$ and $M' := (M \times 1) \cup (\bigsqcup n_0 \partial \Delta_0^4)$, via the map $X \to K$ induced by $\phi$ and the $\phi_0$. Let $\psi: M' \to K$ be the restriction. The 3-manifold $M'$ is triangulated using the given triangulation of $M$ and the standard triangulation of $\partial \Delta_0^4$. The map $\psi$ is simplicial-cellular since $\phi$ and the $\phi_0$ are simplicial-cellular. From the relation $\phi_\#(\zeta_M) - \partial u = 0$, it follows that the 3-simplices of $M'$ whose image under $\psi$ is nonzero in $C_3(K)$ are canceled in pairs in the image under $\psi$. For each canceling pair of 3-simplices of $M'$, we attach a 1-handle to $X$ which joins their barycenters. To do it simplicially, we subdivide relevant 3-simplices as follows.

Recall that the product $\Delta^2 \times [0,1]$ is triangulated by a prism decomposition; see Figure 2. More precisely, ordering vertices of $\Delta^2$ as $\{u_0, u_1, u_2\}$ and vertices of $[0,1]$ as $\{v_0, v_1\}$ and letting $v_{ij} = (u_i, v_j) \in \Delta^2 \times [0,1]$, the standard prism decomposition has 3-simplices $[v_{10}, v_{10}, v_{20}, v_{22}], [v_{00}, v_{10}, v_{11}, v_{21}]$, and $[v_{00}, v_{01}, v_{11}, v_{21}]$. We note that we obtain several different prime decompositions by reordering vertices of $\Delta^2$ and $[0,1]$.
Take a 3-simplex $\Delta'$ embedded in the interior of a standard 3-simplex $\Delta^3$, and subdivide $\partial \Delta^3 \times [0,1] \cong \Delta^3 \setminus \text{int} \Delta'$ by taking a prism triangulation of $\tau \times [0,1]$ for each face $\tau$ of $\Delta^3$. As in Figure 3 one can choose prime decompositions appropriately in such a way that they agree on the intersections. This gives us a subdivision of $\Delta^3$, which contains $\Delta'$ as a simplex. We call $\Delta'$ the inner subsimplex of this subdivision. We apply this subdivision to each 3-simplex of $M'$ whose image under $\psi$ is nonzero in $C_3(K)$, and then attach 1-handles $\Delta^3 \times [0,1]$ to $X$ by identifying $\Delta^3 \times 0$ and $\Delta^3 \times 1$ with inner subsimplices of a canceling pair of 3-simplices. This gives a cobordism $W_3$ between $M = M_3$ and a new 3-manifold $M_2$ obtained from $M'$ by surgery. By triangulating the belt tube $\partial \Delta^3 \times [0,1]$ of each 1-handle using a prism decomposition of (each face of $\Delta^3$) $\times [0,1]$, and by combining it with the subdivision on $M'$, we obtain a triangulation of $M_2$.

Figure 3. A subdivision of a 3-simplex for 1-handle attachment.
$M' \cup \{\text{inner simplices}\}$ to $K^{(2)}$, it follows that $\phi_2$ sends $M_2$ into $K^{(2)}$. This completes the construction of the desired $W_3$, $M_2$ and $\phi_2 : M_2 \to K^{(2)}$.

Now we estimate the complexity of the triangulation of $M_2$. Let $n = d(\zeta_M)$, the complexity of the given triangulation of $M$. Since $u$ has diameter $d(u) = \sum_n |n_n|$, the initial subdivision of $M' = (M \times 1) \sqcup \left( \bigsqcup_n n_n\partial\Delta^4_n \right)$ has complexity $n + 5d(u)$. Since our subdivision in Figure 5 produces 13 3-simplices from one 3-simplex, the complexity of the new subdivision of $M'$ is at most $13(n + 5d(u))$. The number of 1-handles attached is at most $(n + 5d(u))/2$, and each 1-handle attachment removes two 3-simplices (inner sub simplices) and adds $4 \cdot 3 = 12$ 3-simplices (those in the belt tube). Therefore, as claimed, the complexity of the triangulation of $M_2$ is at most

$$n_2 := 12(n + 5d(u)) + 12 \cdot \frac{n + 5d(u)}{2} = 18n + 90d(u).$$

From our construction, it is obvious that $W$ has no 2-handle.

**Proposition 3.11 (Step 2: Reduction to $K^{(1)}$ and complexity estimate).** Suppose $M_2$ is a closed triangulated 3-manifold with complexity $n_2$, which is over $K$ via a simplicial-cellular map $\phi_2 : M_2 \to K^{(1)}$. Then there is another triangulated 3-manifold $M_1$ with complexity at most $n_1 := 21n_2$, which is over $K$ via a simplicial-cellular map $\phi_1 : M_1 \to K^{(1)}$, and there is a bordism $W_2$ over $K$ between $M_2$ and $M_1$ with 2-handle complexity at most $\lfloor n_2/3 \rfloor$.

**Proof.** To obtain $W_2$, we will attach 2-handles to $M_2 \times [0, 1]$ along the inverse image of the barycenter of each 2-simplex of $K$ under $\phi_2$, similarly to Step 2 of Section 3.1. Fix a 2-simplex of $K$ and denote its barycenter by $b$. If the interior of a 3-simplex of $M_2$ meets $\phi_2^{-1}(b)$, then since $\phi_2$ is a simplicial-cellular map, it follows that $\phi_2$ on the 3-simplex is an affine projection $\Delta^3 \to \Delta^2$ onto the 2-simplex sending vertices to vertices; see Figure 4 which illustrates the case $[0, 1, 2, 3] \to [0, 1, 2]$. Figure 4 also shows the pre-image $\phi_2^{-1}(b)$ in the 3-simplex.

![Figure 4. A simplicial projection $\Delta^3 \to \Delta^2$.](image)

We take a sufficiently thin tubular neighborhood $U \cong \phi_2^{-1}(b) \times \Delta^2$ of $\phi_2^{-1}(b)$ in $M_2$ in such a way that the intersection of $U$ and a 3-simplex of $M_2$ is a triangular prism or empty. We triangulate the exterior $M_2 \setminus \text{int}(U)$ by subdividing each 3-simplex with a triangular prism removed as in Figure 5, we first decompose it into one 3-simplex, one triangular prism, and 4 quadrangular pyramids, and then divide the triangular prism and quadrangular pyramids along the dashed lines to obtain a subdivision with $1 + 3 + 4 \cdot 2 = 12$ 3-simplices. Since the subdivision of the two front faces of the original 3-simplex shown in the left of Figure 5 are identical and the two back faces are not subdivided, our subdivisions agree on the intersection of any two such 3-simplices. Observe that $\partial(M_2 \setminus \text{int}(U)) = \partial U$ meets a 3-simplex of $M_2$ in three squares forming a cylinder as in Figure 5, where each square has been triangulated into two 2-simplices. For later use, we note that we can
alter the triangulation of these squares by changing the subdivisions of the quadrangular pyramids and the triangular prism in Figure 5.

Figure 5. A subdivision of a 3-simplex with a triangular prism removed.

Now we consider 2-handle attachment. The pre-image $\varphi^{-1}(b) \subset M_2$ is a disjoint union of piecewise linear circles. Suppose $C$ is a circle component of $\varphi^{-1}(b)$. Let $r$ be the number of 3-simplices of $M_2$ which $C$ passes through as in the local picture shown in Figure 4 that is, $C$ is an $r$-gon. Take a 2-handle $D \times \Delta^2$, where $D$ is a 2-disk. Triangulate $D$ into $r$ triangles by drawing $r$ line segments from the center to the perimeter, and then triangulate $D \times (each face of \Delta^2)$ by ordering the 0-simplices of $D$ and then taking the prism decomposition of (each 2-simplex of $D$) $\times [0, 1]$. Glueing these, we obtain a triangulation of the belt tube $D \times \partial \Delta^2$ of the 2-handle. We attach the 2-handle $D \times \Delta^2$ to $M_2 \times [0, 1]$ by identifying the neighborhood $C \times \Delta^2 \subset M_2 = M_2 \times 1$ with the attaching tube $\partial D \times \Delta^2$. We may assume that the triangulation of $\partial D \times \partial \Delta^2$ agrees with that of $\partial(M \setminus \text{int}(U))$, by altering the latter as mentioned above if necessary. We note that our triangulation of the belt tube of this 2-handle has $3 \cdot 3r = 9r$ 3-simplices.

Attaching 2-handles for each 2-simplex of $K$ in this way, we obtain a cobordism $W_2$ between $M_2$ and another 3-manifold $M_1$, together with a triangulation of $M_1$.

We make $W_2$ a bordism over $K$ similarly to Step 1 above: observe that there is a piecewise linear endomorphism of the 3-simplex $\Delta^3$ shown in the left of Figure 5 which restricts to a simplicial-cellular map of the exterior $\Delta^3 \setminus \text{int}(U)$ onto $A := \partial \Delta^3 \setminus \text{int}(U))$, and is homotopic to the identity rel $A$. From this it follows that the map $\phi_2 : M_2 \to K^{(2)}$ is homotopic to a map, which restricts to a simplicial-cellular map $M_2 \setminus \text{int}(U) \to K^{(1)}$ and extends to $W_2 \to K^{(2)}$. Also, $W_2 \to K^{(2)}$ restricts to a simplicial-cellular map $\phi_1 : M_1 \to K^{(1)}$. In particular $W_2$ is a bordism over $K$ between $(M_2, \phi_2)$ and $(M_1, \phi_1)$.

Now we estimate the complexity of $M_1$. Recall the hypothesis that $M_2$ has $n_2$ 3-simplices. Our subdivision of $M \setminus \text{int}(U)$ has at most $12n_2$ 3-simplices, since each 3-simplex that meets an attaching circle contributes 12 3-simplices as observed above (see Figure 5). Suppose we attach $s$ 2-handles and the $i$th 2-handle is attached along an $r_i$-gon. As observed above, the belt tube of the $i$th 2-handle has $9r_i$ 3-simplices. Therefore our triangulation of $M_1$ has complexity at most $12n_2 + 9(r_1 + \cdots + r_s)$. Since each 3-simplex of $M_2$ can contribute at most one line segment to the attaching circles, we have $r_1 + \cdots + r_s \leq n_2$. It follows that $M_2$ has complexity at most $21n_2$. Since $r_i \geq 3$, we also obtain that $3s \leq n_2$ as claimed. □
**Proposition 3.12** (Step 3: Reduction to $K^{(0)}$ and complexity estimate). Suppose $M_1$ is a closed triangulated 3-manifold with complexity $n_1$, which is over $K$ via a simplicial-cellular map $\phi_1 : M_1 \to K^{(1)}$. Then there is another 3-manifold $M_0$ which is over $K$ via a map $\phi_0 : M_0 \to K^{(0)}$ and there is a bordism $W_1$ over $K$ between $M_1$ and $M_0$ whose 2-handle complexity at most $\lceil n_1/2 \rceil$.

**Proof.** We construct the bordism $W_1$ similarly to Step 3 of Section 3.11 namely by attaching $R_i \times [0, 1]$ to $M_1 \times [0, 1]$, where $R_i$ is a handlebody bounded by a component $S_i$ of the pre-image of the barycenter of a 1-simplex of $K$ under $\phi_1$. Recall from Remark 3.12 that if $S_i$ has genus $g_i$, then attaching $R_i$ is equivalent to attaching $g_i$ 2-handles and one 3-handle.

Since $\phi_1$ is simplicial-cellular, the pre-image $\phi_i^{-1}(b)$ of a barycenter $b$ of a 1-simplex of $K$ intersects a 3-simplex $\Delta^3$ of $M_1$ as shown in Figure 6. We have two possibilities, where $\phi_i^{-1}(b) \cap \Delta^3$ is either a triangle or a quadrangle. By dividing each quadrangle in $\phi_i^{-1}(b)$ into two triangles, we obtain a triangulation of the 2-manifold $\phi_i^{-1}(b)$. Since $M_1$ has $n_1$ 3-simplices and each 3-simplex can contribute at most two triangles to $\phi_i^{-1}(b)$, it follows that the 2-manifold $\bigcup_i S_i$ is has a triangulation with at most $2n_1$ 2-simplices.

![Figure 6. Simplicial projections $\Delta^3 \to \Delta^1$.](image)

To estimate the genera, we invoke the following observation:

**Lemma 3.13.** A connected closed surface admitting a triangulation with $n$ 2-simplices has genus at most $\lceil n^2/2 \rceil$.

**Proof.** Since there are $\frac{3n}{2}$ 1-simplices, the Euler characteristic $2 - 2g = n - \frac{3n}{2} + v$, where $v$ is the number of 0-simplices. Since $v \geq 3$, it follows that $g \leq \frac{n^2}{2}$.

Returning to the proof of Proposition 3.12 suppose the inverse image of the union of the barycenters of 1-simplices of $K$ under $\phi_1$ has $r$ components $S_1, \ldots, S_r$, and suppose $S_i$ has $m_i$ 2-simplices in its triangulation. By Lemma 3.13, the genus $g_i$ of $S_i$ is at most $m_i/4$. Since $m_1 + \cdots + m_r \leq 2n_1$, it follows that $g_1 + \cdots + g_r \leq n_1/2$. Therefore, the 2-handle complexity of $W_1$ is at most $n_1/2$ as claimed.

Now we combine the above three propositions to give a proof of Theorem 3.9.

**Proof of Theorem 3.9**. Let $M_3 = M$ and $\phi_3 = \phi$, and apply Propositions 3.10 and 3.12 to obtain bordisms $W_3$, $W_2$, and $W_1$ together with $(M_2, \phi_2), (M_1, \phi_1)$, and $(M_0, \phi_0)$. Concatenating $W_3$, $W_2$, and $W_1$, we obtain a bordism $W$ over $K$ between $M$ and $N := M_0$. Since $\phi_0$ is into $K^{(0)}$, $\phi_0$ is homotopic to a constant map, and so we may assume that $N$ is trivially over $K$. By Propositions 3.10 and 3.11 and 3.12 $M_2$ and $M_1$ have complexity at most $n_2 := 18n + 90d(u)$ and $n_1 := 21n_2 = 378n + 1890d(u)$, respectively. Also, $W_3$ has no 2-handles, $W_2$ has at most $n_2/3 = 6n + 30d(u)$ 2-handles, and $W_1$ has at
most $n_t/2 = 189n + 945d(u)$ 2-handles. It follows that the 2-handle complexity of $W$ is not greater than

$$6n + 30d(u) + 189n + 945d(u) = 195n + 975d(u).$$

\[\square\]

4. Controlled chain homotopy

In this section we develop some useful results on controlled chain homotopy. We recall basic definitions from the introduction. In this paper we assume that chain complexes are always positive. We also assume that chain complexes are over $\mathbb{Z}$, although everything holds over a ring $R$ endowed with a norm $| \cdot |$. The diameter $d(u)$ of a chain $u$ in a based chain complex is defined to be its $L^1$-norm, that is, if $u = \sum_{\alpha} n_{\alpha} e_{\alpha}$ where $\{e_{\alpha}\}$ is the given basis, then $d(u) = \sum_{\alpha} |n_{\alpha}|$. For a chain homotopy $P: C_\ast \to D_{\ast+1}$ between based chain complexes $C_\ast$ and $D_\ast$, the diameter function $d_P$ of $P$ is defined by

$$d_P(k) := \max\{d(P(c)) \mid c \in C_i \text{ is a basis element, } i \leq k\}.$$ 

If $P$ is a partial chain homotopy which is defined on $C_k$ for $i \leq N$ only, then $d_P(k)$ is defined for $k \leq N$. Note that $d_P(k)$ may not be finite if $\bigoplus_{i \leq k} C_i$ is not finitely generated.

For a function $\delta$ from the domain of $d_P$ to $\mathbb{Z}_{\geq 0}$, we say that $P$ is a $\delta$-controlled (partial) chain homotopy if $d_P(k) \leq \delta(k)$ for each $k$.

Similarly to the chain homotopy case, the diameter function $d_\phi(k)$ of a chain map $\phi: C_\ast \to D_\ast$ is defined by

$$d_\phi(k) = \max\{d(\phi(u)) \mid u \in C_i \text{ is a basis element, } i \leq k\}.$$ 

We say that a chain map $f: C_\ast \to D_\ast$ between based chain complexes $C_\ast$ and $D_\ast$ is based if $f$ takes a basis element to a basis element. A based chain map $\phi$ has $d_\phi(k) = 1$.

For a chain homotopy or a chain map $P$, $d(P(z)) \leq d_P(k) \cdot d(z)$ for any chain $z$ of dimension at most $k$. We state a few more basic facts for later use:

**Lemma 4.1.**

1. (Sum) If $P: \phi \simeq \psi$ and $Q: \zeta \simeq \xi$ for $\phi, \psi, \zeta, \xi: C_\ast \to D_\ast$, then $P+Q: \phi+\zeta \simeq \psi+\xi$ and $d_{P+Q}(k) \leq d_P(k) + d_Q(k)$.

2. (Composition) If $P: \phi \simeq \psi$ and $Q: \zeta \simeq \xi$ for chain maps $\phi, \psi: C_\ast \to D_\ast$ and $\zeta, \xi: D_\ast \to E_\ast$, then $P \circ Q: \phi \simeq \psi$ and $d_{P \circ Q}(k) \leq d_k(k) \cdot d_P(k) + d_Q(k)$.

3. (Tensor product) If $P: \phi \simeq \psi$ and $Q: \zeta \simeq \xi$ for chain maps $\phi, \psi: C_\ast \to D_\ast$ and $\zeta, \xi: C_\ast' \to D_\ast'$, then

$$\Phi(\sigma \otimes \tau) := (P \otimes \zeta + (-1)^{\sigma} \psi \otimes Q)(\sigma \otimes \tau)$$ 

is a chain homotopy $\Phi: \phi \otimes \zeta \simeq \psi \otimes \xi$, and $d_{\Phi}(k) \leq d_P(k) \cdot d_\zeta(k) + d_\psi(k) \cdot d_Q(k)$.

The analogs for partial chain homotopies hold too.

The proof of Lemma 4.1 is straightforward. We omit details.

From Definition 1.20 in the introduction, we recall the notion of a uniformly control family of chain homotopies: suppose $\mathcal{S} = \{P_A: C_A \to D_{A+1} \}_{A \in I}$ is a collection of chain homotopies or a collection of partial chain homotopies defined in dimensions $\leq n$ for some fixed $n$. We say that $\mathcal{S}$ is uniformly controlled by $\delta$ if each $P_A$ is a $\delta$-controlled chain homotopy.

In many cases a family of chain homotopies comes with functoriality, in the following sense. Let $\text{Ch}_\ast$ be the category of positive chain complexes over $\mathbb{Z}$; morphisms are degree zero chain maps as usual. Suppose $\mathcal{C}$ is a category, $F, G: \mathcal{C} \to \text{Ch}_\ast$ are functors, and $\phi, \psi: F \to G$ are natural transformations, that is, for each $A \in \mathcal{C}$ we have chain complexes
Recall that (1) is a conclusion of a standard acyclic model argument. Proof.

\[ \partial P = \delta \text{ is free, we define } (P) \text{ from the standard acyclic model argument: assume } (P_A)_{i=1} \text{ is a family of natural chain homotopies between } \phi \text{ and } \psi \text{ if } P_A : F(A) \to G(A) \text{ is functorial in } A \text{ and } P_A \partial + \partial P_A = \psi_A - \phi_A \text{ for each } A \in \mathcal{C}. \]

The partial chain homotopy analog is defined similarly.

We denote by \( \text{Ch}^b_1 \), the category of positive based chain complexes and (not necessarily based) chain maps. The above paragraph applies to \( \text{Ch}^b_1 \) similarly.

4.1. Controlled acyclic model theorem

Our first source of a uniformly controlled family of natural chain homotopies is the classical acyclic model theorem of Eilenberg and MacLane [EM53].

We recall two basic definitions used to state the standard acyclic model theorem. We say that \( F : \mathcal{C} \to \text{Ch}^b_1 \) (or \( \text{Ch}^b_1 \)) is acyclic with respect to a collection \( \mathcal{M} \) of objects in \( \mathcal{C} \) if the chain complex \( F(A) \) is acyclic for each \( A \in \mathcal{M} \). Also, we say that \( F \) is free with respect to \( \mathcal{M} \) if for each \( i \) there is a collection \( \mathcal{M}_i = \{(A_\lambda, c_\lambda) \}_{\lambda \in \mathcal{M}} \) with \( A_\lambda \in \mathcal{M} \) and \( c_\lambda \in F(A_\lambda)_i \) such that for any object \( B \) in \( \mathcal{C} \), \( F(B)_i \) is a free abelian group and the elements \( F(f)(c_\lambda) \in F(B)_i \) for \( f \in \text{Mor}(A_\lambda, B) \) are distinct and form a basis. We define analogs for based chain complexes:

Definition 4.2. (1) A functor \( F : \mathcal{C} \to \text{Ch}^b_1 \) is based if for any \( f \in \text{Mor}_{\mathcal{C}}(A, B) \), \( F(f) \in \text{Mor}_{\text{Ch}^b_1}(F(A), F(B)) \) is a based chain map. Also, \( F \) is based-acyclic if \( F \) is based and acyclic.

(2) A functor \( F : \mathcal{C} \to \text{Ch}^b_1 \) is based-free with respect to \( \mathcal{M} \) if for each \( i \) there is a collection \( \mathcal{M}_i = \{(A_\lambda, c_\lambda) \}_{\lambda \in \mathcal{M}} \) with \( A_\lambda \in \mathcal{M} \) and \( c_\lambda \in F(A_\lambda)_i \) such that for any \( A \in \mathcal{C} \), the elements \( F(f)(c_\lambda) \in F(A)_i \) for \( f \in \text{Mor}(A_\lambda, A) \) are distinct and form the preferred basis of the based free abelian group \( F(A)_i \). In addition, if \( \mathcal{M}_i \) is finite for each \( i \), then we say that \( F \) is finitely based-free.

Observe that \( F \) is automatically based if \( F \) is based-free.

Theorem 4.3 (Controlled acyclic model theorem). Suppose \( F, G : \mathcal{C} \to \text{Ch}^b_1 \) are functors, \( F \) is finitely based-free with respect to \( \mathcal{M} \), and \( G \) is based-acyclic with respect to \( \mathcal{M} \). Then the following hold.

(1) Any natural transformation \( \phi_0 : H_0 \circ F \to H_0 \circ G \) extends to a natural transformation \( \phi : F \to G \).

(2) Suppose \( \phi, \psi : F \to G \) are natural transformations that induce the same transformation \( H_0 \circ F \to H_0 \circ G \). Then there exist a function \( \delta : \mathbb{Z} \to \mathbb{Z}_{\geq 0} \) and a family of natural chain homotopies \( \{P_A : \phi_A \simeq \psi_A \} \) which is uniformly controlled by \( \delta \).

The key is that that even when the rank of the chain complexes is unbounded, we have a uniform control \( \delta \) if there are only finitely many models in each dimension.

Proof. Recall that (1) is a conclusion of a standard acyclic model argument.

For (2), recall the construction of a family of chain homotopies

\[ P_A = \{(P_A)_i : F(A)_{i-1} \to G(A)_i \}, \quad A \in \mathcal{C} \]

from the standard acyclic model argument: assume \( (P_A)_{i-1} \) has been defined. Using that \( G(A_\lambda) \) is acyclic for each \( (A_\lambda, c_\lambda) \in \mathcal{M}_i \), we obtain a chain, which we denote by \( (P_A)_i(c_\lambda) \in G(A_\lambda)_{i+1} \) as abuse of notation for now, that makes the equation \( P_A \partial + \partial P_A = \psi_A - \phi_A \) satisfied at \( c_\lambda \in F(A_\lambda)_i \); then for an arbitrary \( A \in \mathcal{C} \), using that \( F \) is free, we define \( (P_A)_i \) on a basis element by \( (P_A)_i(F(f)(c_\lambda)) := G(f)((P_A)_{i-1}(c_\lambda)) \) and extend it linearly.
Since \( G(f) \) is based, the diameter of \((P_A)_i(F(f)(c_A))\) is equal to that of \((P_A)_i(c_A)\). Since \( F(A)_i \) is based by \( \{F(f)(c_A)\}\), it follows that for any \( A \in \mathcal{C} \) the diameter function \( d_{P_A} \) of \( P_A \) is equal to the function \( \delta \) defined by

\[
\delta(k) := \max \{d((P_A)_i(c_A)) \mid i \leq k, (A, c_A) \in \mathcal{M}_i\}.
\]

The value \( \delta(k) \) is finite for any \( k \), since \( \mathcal{M}_i \) is a finite collection for any \( i \). \( \square \)

The proof of Theorem 4.3 tells us that the control function \( \delta(k) \) is obtained from the diameter of the chain homotopy on the models. Using this, we can often compute \( \delta(k) \) explicitly, at least for small \( k \). We deal with an example in the next subsection.

### 4.2. Controlled Eilenberg-Zilber theorem

In this subsection, we investigate uniform control for the chain homotopies of the Eilenberg-Zilber theorem for products. Our result is best described using simplicial sets. Readers not familiar with simplicial sets may refer to our quick review of basic definitions in the appendix.

We first state a theorem, and then recall the terminologies used in the statement for the reader’s convenience.

**Theorem 4.4** (Controlled Eilenberg-Zilber Theorem). For simplicial sets \( X \) and \( Y \), let

\[
\Delta_{X,Y} : C_*(X \times Y) \to C_*(X) \otimes C_*(Y)
\]

\[
\nabla_{X,Y} : C_*(X) \otimes C_*(Y) \to C_*(X \times Y)
\]

be the Alexander-Whitney map and the shuffle map. Then there is a natural family of chain homotopies

\[
\{P_{X,Y} : \nabla_{X,Y} \circ \Delta_{X,Y} \simeq \text{id}_{C_*(X \times Y)} \mid X \text{ and } Y \text{ are simplicial sets}\}
\]

which is uniformly controlled by a function \( \delta_{EZ}(k) \). Furthermore, the value of \( \delta_{EZ}(k) \) for \( k \leq 4 \) is as follows.

<table>
<thead>
<tr>
<th>( k )</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \delta_{EZ}(k) )</td>
<td>0</td>
<td>4</td>
<td>11</td>
<td>26</td>
<td></td>
</tr>
</tbody>
</table>

**Remark 4.5.**

1. Of course the existence of the chain homotopy \( P_{X,Y} \) is due to Eilenberg-Zilber [EM53]. What Theorem 4.3 newly gives is an addendum that \( \{P_{X,Y}\} \) is uniformly controlled, and that the values of the control function \( \delta_{EZ} \) are as above.

2. In our applications, explicit values of \( \delta_{EZ}(k) \) for \( k \leq 3 \) are sufficient, since we are interested in chains arising from 3-manifolds.

Recall, for instance from the appendix, that a simplicial set \( X \) consists of sets \( X_n \) (\( n = 0, 1, \ldots \)), face maps \( d_i : X_n \to X_{n-1} \), and degeneracy maps \( s_i : X_n \to X_{n+1} \) (\( i = 0, 1, \ldots, n \)). We call \( \sigma \in X_n \) an \( n \)-simplex of \( X \). Let \( ZX \) be the simplicial abelian group generated by \( X \), and denote its (unnormalized) Moore complex by \( ZX_* \). In other words, \( ZX_n \) is the free abelian group generated by \( X_n \), and the boundary map \( \partial : ZX_n \to ZX_{n-1} \) is defined by \( \partial \sigma = \sum_i (-1)^i d_i \sigma \) for \( \sigma \in X_n \). We always view \( ZX_* \) as a based chain complex; each \( ZX_n \) is based by the \( n \)-simplices. We denote the homology by \( H_*(X) := H_*(ZX_*) \).

For two simplicial sets \( X \) and \( Y \), the product \( X \times Y \) is defined by \( (X \times Y)_n := X_n \times Y_n \); writing \( \sigma \times \tau := (\sigma, \tau) \in X_n \times Y_n \), the face and degeneracy maps are defined by \( d_i(\sigma \times \tau) = d_i \sigma \times d_i \tau \) and \( s_i(\sigma \times \tau) = s_i \sigma \times s_i \tau \).
The Alexander-Whitney map
\[ \Delta = \Delta_{X,Y} : \mathbb{Z}(X \times Y)_* \longrightarrow \mathbb{Z}X_* \otimes \mathbb{Z}Y_* \]
is defined by
\[ (4.1) \quad \Delta(\sigma \otimes \tau) = \sum_{i=0}^n d_{i+1} \cdots d_n \sigma \otimes (d_0)^i \tau \]
for \( \sigma \otimes \tau \in X_n \times Y_n \). To define its chain homotopy inverse, we use the following notation.

A \((p,q)\)-shuffle \((\mu, \nu) = (\mu_1, \ldots, \mu_p, \nu_1, \ldots, \nu_q)\) is a permutation of \((1, \ldots, p + q)\) such that \(\{\mu_i\}, \{\nu_i\}\) are both increasing. Let \(\epsilon(\mu, \nu)\) be the sign of the permutation, and \(S_{p,q}\) be the set of \((p,q)\)-shuffles. Then the shuffle map (or the Eilenberg-Zilber map or the Eilenberg-MacLane map)
\[ \nabla = \nabla_{X,Y} : \mathbb{Z}X_* \otimes \mathbb{Z}Y_* \longrightarrow \mathbb{Z}(X \times Y)_* \]
is defined by
\[ (4.2) \quad \nabla(\sigma \otimes \tau) = \sum_{(\mu, \nu) \in S_{p,q}} (-1)^{\epsilon(\mu, \nu)} (s_{\nu_1} \cdots s_{\nu_q} \sigma) \times (s_{\mu_p} \cdots s_{\mu_1} \tau) \]
for \( \sigma \otimes \tau \in \mathbb{Z}X_p \otimes \mathbb{Z}Y_q \).

It is verified straightforwardly that \(\Delta\) and \(\nabla\) are chain maps and \(\Delta \circ \nabla = id\) on \(\mathbb{Z}X_* \otimes \mathbb{Z}Y_*\). It is known that \(\nabla \circ \Delta\) is chain homotopic to \(id\) on \(\mathbb{Z}(X \times Y)_*\), by an acyclic model argument with \(\mathcal{M} = \{\Delta^n \times \Delta^n \mid n \geq 0\}\) as models. By using our controlled version of the acyclic model theorem (Theorem 4.4), we can obtain the additional conclusions on the chain homotopy \(\nabla \circ \Delta \simeq id\) as stated in Theorem 4.4. We describe details below.

**Proof of Theorem 4.4**

We follow the standard acyclic model argument for a product. Let \(s\mathbf{Set}\) be the category of simplicial sets, and define a functor \(F : s\mathbf{Set} \times s\mathbf{Set} \rightarrow \mathbf{Ch}_+^b\) by \(F(X,Y) := \mathbb{Z}(X \times Y)_*\). By definition, \(F\) is based. Let \(\Delta^n\) be the standard \(n\)-simplex as a simplicial set; we write a \(k\)-simplex of \(\Delta^n\) as a sequence \([v_0, \ldots, v_k]\) of integers \(v_i\) such that \(0 \leq v_0 \leq \cdots \leq v_k \leq n\). Let \(\mathcal{M} = \{\Delta^n, \Delta^n \mid n \geq 0\}\). Then \(F\) is acyclic with respect to \(\mathcal{M}\), since \(\Delta^n \times \Delta^n\) is contractible. Also, \(F\) is finitely based-free with respect to \(\mathcal{M}\) since \(\mathbb{Z}(X \times Y)_n\) is freely generated by \(\{f[0, \ldots, n] \times g[0, \ldots, n] \in (X \times Y)_n \mid f : \Delta^n \rightarrow X, g : \Delta^n \rightarrow Y\} \) are morphisms).

Note that there is only one model \((\Delta^n, \Delta^n)\) in each dimension \(n\).

By Theorem 4.4 it follows that there is a function \(\delta_{\mathbb{E}Z}(k)\) and a natural family of chain homotopies \(P_{X,Y} : \mathbb{Z}(X \times Y)_* \rightarrow \mathbb{Z}(X \times Y)_{*+1}\) between \(\nabla_{X,Y} \circ \Delta_{X,Y}\) and \(id\), which is uniformly controlled by \(\delta_{\mathbb{E}Z}\).

We will explicitly compute the value \(\delta_{\mathbb{E}Z}(k)\) for small \(k\). For convenience, denote
\[ P_k := (P_{\Delta^+, \Delta^k})_k : \mathbb{Z}(\Delta^k \times \Delta^k)_k \longrightarrow \mathbb{Z}(\Delta^k \times \Delta^k)_{k+1}. \]
The proof of Theorem 4.4 tells us that \(\delta_{\mathbb{E}Z}(k)\) is exactly the diameter of the chain \(P_k([0, \ldots, k] \times [0, \ldots, k])\), where \(P_k([0, \ldots, k] \times [0, \ldots, k])\) is defined inductively as follows: assuming that \(P_{k-1}([0, \ldots, k-1] \times [0, \ldots, k-1])\) has been defined, \(P_k\) is determined by naturality and \(P_k([0, \ldots, k] \times [0, \ldots, k]) \in \mathbb{Z}(\Delta^k \times \Delta^k)_{k+1}\) is defined to be a solution \(x\) of the system of linear equations
\[ (4.3) \quad \partial x = (-P_{k-1} \partial + \nabla \circ \Delta - id)([0, \ldots, k] \times [0, \ldots, k]) \]
where \(\partial : \mathbb{Z}(\Delta^k \times \Delta^k)_{k+1} \rightarrow \mathbb{Z}(\Delta^k \times \Delta^k)_k\) is viewed as a linear map.
We remark that

$$\text{rank}(\Delta^k \times \Delta^k)_{k+1} = \binom{2k+2}{k} \quad \text{and} \quad \text{rank}(\Delta^k \times \Delta^k)_k = \binom{2k+1}{k},$$

that is, the system (4.3) consists of \(\binom{2k+1}{k}\) linear equations in \(\binom{2k+2}{k}\) variables. It can be seen that the ranks grow exponentially, by using Stirling’s formula. Fortunately for small \(k\) we can still find (or at least verify) solutions. We describe details below.

For \(k = 0\), \(P_0([0] \times [0]) = 0\) satisfies (4.3) since \(\nabla \circ \Delta = \text{id} \circ \Delta\) on \(\mathbb{Z}(\Delta^0 \times \Delta^0)\). From this it follows that \(\delta_{EZ}(0) = 0\).

For \(k = 1\), straightforward computation shows that

$$\nabla \Delta([0, 1] \times [0, 1]) = \nabla([0] \otimes [0, 1] + [0, 1] \otimes [1]) = [0, 0] \times [0, 1] + [0, 1] \times [1, 1].$$

Since it is equal to \(\partial([0, 0, 1] \times [0, 1, 1])\), \(P_1([0, 1] \times [0, 1]) := [0, 0, 1] \times [0, 1, 1]\) is a solution of (4.3). Since this is a chain of diameter one, we have \(\delta_{EZ}(1) = 1\).

For \(k = 2\), we have that

$$\nabla \Delta([0, 1, 2] \times [0, 1, 2]) = \nabla([0] \otimes [0, 1, 2] + [0, 1] \otimes [1, 2] + [0, 1, 2] \otimes [2])$$

$$= [0, 0, 0] \times [0, 1, 2] - [0, 0, 1] \times [1, 2, 2]$$

$$+ [0, 1, 1] \times [1, 1, 2] + [0, 1, 2] \times [2, 2, 2]$$

and that

$$P_2 \partial([0, 1, 2] \times [0, 1, 2]) = P_1([1, 2] \times [1, 2] - [0, 2] \times [0, 2] + [0, 1] \times [0, 1])$$

$$= [1, 1, 2] \times [1, 2, 2] - [0, 0, 2] \times [0, 2, 2] + [0, 0, 1] \times [0, 1, 1].$$

Using these, it is straightforward to verify that

$$P_2([0, 1, 2] \times [0, 1, 2]) = -[0, 0, 0, 1] \times [0, 1, 2, 2] + [0, 0, 1, 1] \times [0, 1, 1, 2]$$

$$+ [0, 0, 1, 2] \times [0, 2, 2, 2] - [0, 1, 1, 2] \times [0, 1, 2, 2]$$

is a solution of (4.3). Since its diameter is 4, we have \(\delta_{EZ}(2) = 4\).

For \(k = 3\), (4.3) is a system of 1225 linear equations in 3136 variables. Aided by a computer, we found the following solution of (4.3):

$$P_3([0, 1, 2, 3] \times [0, 1, 2, 3]) = [0, 0, 0, 0, 1] \times [0, 1, 2, 3, 3] - [0, 0, 0, 1, 1] \times [0, 1, 2, 2, 3]$$

$$+ [0, 0, 0, 1, 2] \times [0, 2, 3, 3, 3] + [0, 0, 1, 1, 1] \times [0, 1, 1, 2, 3]$$

$$- [0, 0, 1, 1, 2] \times [0, 2, 2, 3, 3] + [0, 0, 1, 2, 2] \times [0, 2, 2, 2, 3]$$

$$+ [0, 0, 1, 2, 3] \times [0, 3, 3, 3, 3] + [0, 1, 1, 1, 2] \times [0, 1, 2, 3, 3]$$

$$- [0, 1, 1, 2, 2] \times [0, 1, 2, 2, 3] - [0, 1, 1, 2, 3] \times [0, 1, 3, 3, 3]$$

$$+ [0, 1, 2, 2, 3] \times [0, 1, 2, 3, 3].$$

We remark that we can verify by hand that it is a solution of (4.3). From this it follows that \(\delta_{EZ}(3) = d(P_3([0, 1, 2, 3] \times [0, 1, 2, 3])) = 11\).
For \( k = 4 \), our computation fully depends on a computer. A solution of the system (4.3), which has 15876 equations in 44100 variables in this case, is given by

\[
P_4([0, 1, 2, 3, 4] \times [0, 1, 2, 3, 4]) =
\]

\[
- [0, 0, 0, 0, 0, 1] \times [0, 1, 2, 3, 4, 4] + [0, 0, 0, 0, 1, 1] \times [0, 1, 2, 3, 4, 4] \\
+ [0, 0, 0, 1, 1, 2] \times [0, 2, 3, 4, 4, 4] - [0, 0, 0, 1, 1, 1] \times [0, 1, 2, 2, 3, 4] \\
- [0, 0, 0, 1, 1, 2] \times [0, 2, 3, 4, 4, 4] + [0, 0, 0, 1, 2, 2] \times [0, 2, 3, 3, 4] \\
- [0, 0, 0, 1, 2, 3] \times [0, 3, 4, 4, 4, 4] + [0, 0, 1, 1, 1, 1] \times [0, 1, 2, 3, 4] \\
+ [0, 0, 1, 1, 1, 2] \times [0, 2, 2, 3, 4, 4] - [0, 0, 0, 1, 2, 2] \times [0, 2, 2, 3, 4] \\
+ [0, 0, 1, 1, 2, 3] \times [0, 3, 3, 4, 4, 4] + [0, 0, 0, 1, 2, 2] \times [0, 2, 2, 3, 4] \\
- [0, 0, 1, 2, 2, 3] \times [0, 3, 3, 3, 4, 4] + [0, 0, 1, 2, 3, 3] \times [0, 3, 3, 3, 4, 4] \\
+ [0, 0, 1, 2, 3, 4] \times [0, 3, 4, 4, 4, 4] - [0, 0, 0, 1, 1, 2] \times [0, 1, 2, 3, 4, 4] \\
+ [0, 0, 0, 1, 2, 3] \times [0, 3, 4, 4, 4, 4] - [0, 0, 0, 1, 1, 2] \times [0, 1, 1, 2, 3, 4] \\
- [0, 1, 1, 2, 2, 3] \times [0, 1, 2, 3, 4, 4] + [0, 1, 1, 2, 3, 3] \times [0, 1, 3, 3, 4, 4] \\
- [0, 1, 1, 2, 3, 4] \times [0, 1, 3, 3, 4, 4] - [0, 1, 1, 2, 3, 4] \times [0, 1, 4, 4, 4, 4] \\
+ [0, 1, 2, 2, 3] \times [0, 1, 2, 3, 3, 4] + [0, 1, 2, 2, 3, 3] \times [0, 1, 2, 3, 3, 4] \\
+ [0, 1, 2, 2, 3, 4] \times [0, 1, 2, 4, 4, 4] - [0, 1, 2, 3, 3, 4] \times [0, 1, 2, 3, 4, 4].
\]

It follows that \( \delta_{EZ}(4) = 26 \).

**Remark 4.6.** In spite of Remark 4.6, it would be nicer if we had an explicit closed formula for \( P_k([0, \ldots, k] \times [0, \ldots, k]) \) for general \( k \); this would give a general formula for the chain homotopy \( P_XY \) for any \( X, Y \), and possibly a closed formula for \( \delta_{EZ}(k) \). The author does not know the answer.

### 4.3. Conjugation on groups

Recall that for a group \( G \), the (unnormalized) Moore complex \( ZBG_* \) associated to the simplicial classifying space \( BG \) (which is a simplicial set) can be used to compute the group homology \( H_*(G) \) with integral coefficients. For example, see the appendix [§2] and [§4]. In fact \( ZBG_* \) is equal to the unnormalized bar resolution tensored with \( \bbZ \). An explicit description of \( ZBG_* \) is as follows: \( ZBG_n \) is the free abelian group generated by \( BG_n := \{ [g_1, \ldots, g_n] \mid g_i \in G \} \), and the boundary map \( \partial : ZBG_n \to ZBG_{n-1} \) is given by \( \partial c = \sum_{i=0}^n (-1)^{i+1} d_i c \), where \( d_i \) is defined by

\[
d_i[g_1, \ldots, g_n] = \begin{cases} 
g_2, \ldots, g_n & \text{if } i = 0, \\
g_1, \ldots, g_{i-1}, g_i g_{i+1}, g_{i+2}, \ldots, g_n & \text{if } 0 < i < n, \\
g_1, \ldots, g_{n-1} & \text{if } i = n. \end{cases}
\]

As abuse of notation, for a group homomorphism \( f \), we denote by \( f \) the induced based chain map on \( \bbZ B(-)_* \), that is, \( f[g_1, \ldots, g_n] = [f(g_1), \ldots, f(g_n)] \).

It is well known that for any group \( G \) and \( g \in G \), the conjugation homomorphism

\[
\mu_g : G \to G
\]

defined by \( \mu_g(h) = h^g := hgh^{-1} \) induces the identity map on \( H_*(G) \). For example, see [Wol94, p. 191, Theorem 6.7.8]. In the following theorem, we give a chain level statement in terms of controlled chain homotopies, from which the homological statement is immediately obtained.
Theorem 4.7. There is a family of chain homotopies

\[ \{ S_{G,g} : \text{id}_{ZBG} \sim \mu_g \mid G \text{ is a group, } g \in G \} \]

which is uniformly controlled by the function \( \delta_{\text{conj}}(k) := k + 1 \). The chain homotopy \( S_{G,g} \) is natural with respect to \((G,g)\), in the sense that \( fS_{G,g} = S_{f(G),f(g)}f \) for any homomorphism \( f : G \to \Gamma \).

To motivate our chain homotopy construction for Theorem 4.7, we recall a geometric interpretation of an \( n \)-simplex \([g_1, \ldots, g_n]\) of \( \text{BG} \) that arises from the nerve construction for \( G \): there is exactly one \( 0 \)-simplex \([\]\] in \( \text{BG} \) which is the basepoint, and for \( n > 0 \), \([g_1, \ldots, g_n]\) \( \in \text{BG} \) corresponds to an (possibly degenerate) \( n \)-simplex \([v_0, \ldots, v_n]\) in the geometric realization of \( \text{BG} \) whose edge \([v_{i-1}, v_i]\) is a loop representing \( g_i \in \pi_1(\text{BG}) = G \).

Consider a prism \( \Delta^n \times [0,1] \). For convenience, we write \( \Delta^n = [e_0, \ldots, e_n] \), and denote the vertices of \( \Delta^n \times [0,1] \) by \( v_{ij} = (e_i, j) \), \( i = 0, \ldots, n \), \( j = 0, 1 \). If there is a geometric homotopy from \( \text{id}_{\text{BG}} \) to the conjugation \( \mu_g \), then the restriction on a simplex \([g_1, \ldots, g_n]\) should give a map of \( \Delta^n \times [0,1] \) that sends the edges \([v_{i(1-1)}, v_{i0}]\) and \([v_{i(1-1)}, v_{i1}]\) to \( g_i \) and \( \mu_g(g_i) = g_i^g \) respectively. This tells us what the restriction \( \Delta^n \times [0,1] \to \text{BG} \) should be. The standard prism decomposition divides the product \( \Delta^n \times [0,1] \) into \( n+1 \) simplices. It turns out that, for instance as illustrated in Figure 7 for \( n = 2 \), we can label edges of the resulting simplices in such a way that the prescribed \( \Delta^n \times [0,1] \to \text{BG} \) extends to \( \Delta^n \times [0,1] \) simplicially. Note that in Figure 7 each path \( e_i \times [0,1] \) is sent to the loop \( g^{-1} \), so that the basepoint change effect of the homotopy is exactly the conjugation by \( g \) on \( \pi_1(\text{BG}) = G \).

![Figure 7. Prism decomposition of a homotopy for conjugation.](image)

Generalizing Figure 7 to an arbitrary dimension \( n \), we obtain the chain homotopy formula used in the formal proof of Theorem 4.7 given below.

Proof of Theorem 4.7. For a group \( G \) and an element \( g \in G \), we define a chain homotopy

\[ S = S_{G,g} : ZBG_* \to ZBG_{*+1} \]

by

\[ S[g_1, \ldots, g_n] = \sum_{i=0}^{n} (-1)^i [g_1, \ldots, g_i, g_i^{-1}, g_{i+1}^g, \ldots, g_n^g]. \]

By a straightforward computation it is verified that \( S\partial + \partial S = \mu_g - \text{id} \). From the defining formula, it follows that \( S_{G,g} \) is natural and that \( d_{S_{G,g}}(k) \leq k + 1 \). \( \square \)
5. Chain homotopy for embeddings into mitoses

We begin by recalling a definition of Baumslag, Dyer, and Heller to set up notations. As before, we write $g^h := hgh^{-1}$.

Definition 5.1 (BDH80). Suppose $G$ is a group. A group $M$ endowed with an embedding $ι: G → M$ is a mitosis of $G$ if there are elements $u, t ∈ M$ such that $M$ is generated by $ι(G) ∪ \{u, t\}$ and $g^t = gg^n, [h, g^n] = e$ for any $g, h ∈ ι(G)$. In particular, define

$m(G) := \langle G, u, t \mid [h, g^n] = e, g^t = gg^n \text{ for any } g, h ∈ G \rangle$.

Then $m(G)$ together with the natural embedding $k_G: G → m(G)$ is a mitosis of $G$.

Define $\mathbb{A}^0(G) = G$, $\mathbb{A}^n(G) := m(\mathbb{A}^{n-1}(G))$ for $n ≥ 1$ inductively. We denote by $ι^n_G: G → \mathbb{A}^n(G)$ the composition $k_{\mathbb{A}^{n-1}(G)} ∘ \cdots ∘ k_{\mathbb{A}(G)} ∘ k_G$.

As observed in [BDH80], it is verified straightforwardly that (i) $m: Gp → Gp$ is a functor of the category $Gp$ of groups, (ii) $k_G$ is a natural transformation $id_{Gp} → m$ which is injective for each $G$, and (iii) $m(f): m(G) → m(Γ)$ is injective whenever $f: G → Γ$ is an injective group homomorphism. Consequently (i), (ii), and (iii) hold for $(\mathbb{A}^n, ι^n_G)$ in place of $(m, k_G)$.

In [BDH80], they showed that if $k$ is a field, then the map $H_i(G; k) → H_i(\mathbb{A}^n(G); k)$ induced by $ι^n_G$ is zero for $i = 1, \ldots, n$. Our main aim of this section is to prove the following chain level result (Theorem 5.2), which particularly gives this homological result of [BDH80] as an immediate consequence.

We denote the trivial group homomorphism by $e_{π, G}: π → G$. When the groups $π$ and $G$ are understood from the context, we write $e = e_{π, G}$ by dropping $π, G$ from the notation. Recall that we denote by $f: \mathbb{Z}BG → \mathbb{Z}BG^*$ the chain map induced by a group homomorphism $f: G → Γ$.

Theorem 5.2. For each $n$, there is a family

$$\{Φ^n_G: e ≃ ι^n_G \mid G \text{ is a group}\}$$

of partial chain homotopies $Φ^n_G$ defined in dimension $≤ n$, between the chain maps $e, ι^n_G: \mathbb{Z}BG → \mathbb{Z}BG^*$, which is uniformly controlled by a function $δ_{BDH}$. For $k ≤ 4$, the value of $δ_{BDH}(k)$ is as follows:

<table>
<thead>
<tr>
<th>$k$</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
</tr>
</thead>
<tbody>
<tr>
<td>$δ_{BDH}(k)$</td>
<td>0</td>
<td>6</td>
<td>26</td>
<td>186</td>
<td>3410</td>
</tr>
</tbody>
</table>

A precise definition of $δ_{BDH}$ will be given in Definition 5.7. Note that the control function $δ_{BDH}$ is independent of $n$. The values of $δ_{BDH}(k)$ for $k ≤ 3$ will be essential in proving Theorem 5.2 stated in the introduction.

The remainder of this section is devoted to the proof of Theorem 5.2. As a preliminary, we make some observations on the product of groups. From the definition, for groups $G$ and $H$, we have $B(G × H) = BG × BH$ as simplicial sets. Let

$$Δ = Δ_{BG, BH}: \mathbb{Z}(BG × BH)^* → \mathbb{Z}BG^* ⊗ \mathbb{Z}BH^*$$

be the Alexander-Whitney map. We define

$$Λ_G, Λ_H, Λ: \mathbb{Z}(BG × BH)^* → \mathbb{Z}BG^* ⊗ \mathbb{Z}BH^*$$

by

$$Λ_G(σ × τ) := σ ⊗ (d_0)^nτ = σ ⊗ []$$

$$Λ_H(σ × τ) := d_1 ⋯ d_nσ ⊗ τ = [] ⊗ τ,$$
Lemma 5.4. Suppose \( \sigma \times \tau \in (BG \times BH)_n \), and by \( \Lambda := \Delta - \Lambda_G - \Lambda_H \). Note that if \( n \geq 1 \), \( \Lambda_H \) and \( \Lambda_G \) are the first and last term of the defining formula (4.1) of \( \Delta \) respectively. Consequently, \( \Lambda \) is the sum of the remaining terms.

**Lemma 5.3.** The maps \( \Lambda_G, \Lambda_H, \) and \( \Lambda \) are chain maps.

**Proof.** Since
\[
\Lambda_H \partial(\sigma \times \tau) = \Delta_H \left( \sum \frac{(-1)^i d_i \sigma \times d_i \tau}{i} \right) = \sum \frac{(-1)^i (\llbracket \partial d_i \tau \rrbracket)}{i} = \llbracket \partial \tau \rrbracket = \partial \Lambda_H(\sigma \times \tau),
\]
we have that \( \Lambda_H \) is a chain map. A similar argument works for \( \Lambda_G \). Since \( \Delta \) is a chain map, it follows that \( \Lambda = \Delta - \Lambda_G - \Lambda_H \) is a chain map. \( \square \)

For the next lemma, recall that \( \delta_{EZ}(k) \) is the control function in Theorem 4.4.

**Lemma 5.4.** Suppose \( f: G \rightarrow K \) and \( g: H \rightarrow L \) are group homomorphisms. Suppose \( Q: e \simeq f \) is a partial chain homotopy defined in dimension \( \leq n-1 \) between \( e, f: ZBG_* \rightarrow \mathbb{Z}BK_* \), that is, \( Q \partial + \partial Q = f - e \) on \( ZBG_i \) for \( i \leq n-1 \). Suppose \( Q_0 \equiv 0 \) on \( ZBG_0 \). Consider the product homomorphisms
\[
f \times g, f \times e, e \times g: G \times H \rightarrow K \times L
\]
and the induced chain maps \( Z(BG \times BH)_* \rightarrow Z(BK \times BL)_* \). Let \( P = P_{BK, BL}: \nabla \Delta \simeq \text{id} \) be the chain homotopy in Theorem 4.4. Then
\[
T := P(f \times g - e \times g) + \nabla(Q \otimes g)\Lambda: Z(BG \times BH)_* \rightarrow Z(BK \times BL)_{*+1}
\]
is a partial chain homotopy defined in dimension \( \leq n \). Furthermore it satisfies that \( T_0 = 0 \) on \( C_0(BK \times BL) \), that is,
\[
d_T(0) = 0, \quad d_T(k) \leq 2 \cdot \delta_{EZ}(k) + (k-1) \left( \frac{k}{[k/2]} \right) \cdot d_Q(k-1) \quad \text{for } k \geq 1.
\]

We remark that \( \Delta, \Lambda, \) and \( \nabla \) in the above statements are those for the product of \( BK \) and \( BL \).

**Proof.** By Lemma 4.3, we have that \( Q \otimes g: e \otimes g \simeq f \otimes g \) is a partial chain homotopy. More precisely, on \( \sum_{i<n} ZBG_i \otimes ZBH_i, \)
\[
(Q \otimes g) \partial + \partial (Q \otimes g) = Q \partial \otimes g + Q \otimes g \partial + \partial Q \otimes g = Q \otimes g.
\]
(5.1)

By the definitions, for any \( f \) and \( g \), the following diagram commutes:
\[
\begin{array}{ccc}
Z(BG \times BH)_* & \xrightarrow{f \times g} & Z(BK \times BL)_*
\end{array}
\]
\[
\begin{array}{ccc}
\Delta & \xrightarrow{} & \Delta
\end{array}
\]
\[
\begin{array}{ccc}
ZBG_* \otimes ZBH_* & \xrightarrow{f \otimes g} & ZBK_* \otimes ZBL_*
\end{array}
\]

We also have
\[
\nabla(f \otimes g) \Lambda_G(\sigma \times \tau) = \nabla(f \otimes g)(\sigma \otimes \llbracket \rrbracket) = \nabla(f \sigma \otimes \llbracket \rrbracket) = (f \times e)(\sigma \times \tau),
\]
for any \( f \) and \( g \). Similarly
\[
\nabla(f \otimes g) \Lambda_H = e \times g.
\]
(5.4)
Now, on $\mathbb{Z}(BG \times BH)_k$ with $1 \leq k \leq n$, we have
\[
\begin{align*}
f \times g - e \times g & \simeq \nabla \Delta(f \times g - e \times g) & \text{by Theorem 4.4} \\
& = \nabla(f \otimes g - e \otimes g)\Delta & \text{by (5.2)} \\
& = \nabla(f \otimes g - e \otimes g)(\Lambda G + \Lambda H + \Lambda) & \text{by definitions} \\
& = (f \times e - e \times e) + (e \times g - e \times g) + \nabla \{(Q \otimes g)\partial + \partial(Q \otimes g)\} & \text{by (5.3), (5.4), and (5.1)} \\
& + \nabla((Q \otimes g)\partial + \partial(Q \otimes g)\Lambda) & \text{by Lemma 5.3}
\end{align*}
\] (5.5)

Note that in (5.5) we can apply (5.1) since the image of $\mathbb{Z}(BG \times BH)_k$ under $\Lambda$ lies in $\sum_{k=1}^{k-1} \mathbb{Z}BG_i \otimes \mathbb{Z}BH_k$.

On $\mathbb{Z}(BG \times BH)_0$, we have $f \times g - e \times g = 0 = f \times e - e \times e$.

Let $P = P_{B_K,B_L}$ be the chain homotopy given by Theorem 4.4 and let
\[
T := P(f \times g - e \times g) + \nabla(Q \otimes g)\Lambda.
\]

Note that $T_0 = 0$ on $\mathbb{Z}(BG \times BH)_0$ since $Q_0 = 0$. From (5.5) and Lemma 5.1 (1), (2), it follows that $T$ is a partial chain homotopy between $(f \times e - e \times e) + (e \times g - e \times e)$ and $f \times g - e \times e$ in dimension $\leq n$.

Now we estimate the diameter $d_T(k)$ of $T$. The chain maps $f \times g$ and $e \times g$ have diameter function $\equiv 1$. Observe that the defining formula (4.2) for $\nabla$ has $\binom{p+q}{p}$ summands, since the number of $(p,q)$-shuffles is $\binom{p+q}{p}$. It follows that $d \nabla(k) \leq \binom{k}{k/2}$. Similarly, from the defining formula (4.11) for $\nabla$, it follows that $d \Lambda(k) = k - 1$. Note that $d_{Q \otimes g}\Lambda(k) \leq d_{Q}(k-1) \cdot d_{\Lambda}(k)$ since the $Q$ factor in the expression $(Q \otimes g)\Lambda$ is applied to only chains of dimension at most $k - 1$. Combining the above observations using Lemma 5.3 we obtain the claimed estimate for $d_T(k)$.

**Remark 5.5.** A reduced simplicial set is defined to be a simplicial set with a unique 0-simplex. Lemmas 5.3 and 5.4 hold for reduced simplicial sets, although we stated and proved them for classifying spaces of groups only. The proofs are identical.

We use the above results to show a key property of the mitosis embedding $k_G : G \to m(G)$ on the chain level.

**Theorem 5.6.** Suppose $\phi : \pi \to G$ is a group homomorphism and $Q : e \simeq \phi$ is a partial chain homotopy defined in dimension $\leq n - 1$ between $e, \phi : \mathbb{Z}B\pi_* \to \mathbb{Z}BG_*$ such that $Q_0 = 0$ on $\mathbb{Z}B\pi_0$. Then there is a partial chain homotopy $R : e \simeq k_G \circ \phi$ defined in dimension $\leq n$ between $e, k_G \circ \phi : \mathbb{Z}B\pi_* \to \mathbb{Z}Bm(G)_*$. In addition, $R_0 = 0$ on $\mathbb{Z}B\pi_0$, that is, $d_R(0) = 0$, and
\[
d_R(k) \leq 2(k + 1) + 2 \cdot d_{\hat{E}Z}(k) + (k - 1) \left( \frac{k}{k/2} \right) \cdot d_{Q}(k - 1) \quad \text{for } k \geq 1.
\]

**Proof.** Recall that
\[
m(G) = \langle G, u, t \mid [h, g^n] = e, g^t = gg^u \text{ for any } g, h \in G \rangle.
\]
Define inclusions $i, j : D : \pi \to \pi \times \pi$ by $i(g) = (g, e)$, $j(g) = (e, g)$, and $D(g) = (g, g)$. Define $f : G \times G \to m(G)$ by $f(g, h) = gh^u$. Recall $\mu_g(h) = h^g$ denotes the conjugation
by $g$. Consider the following diagram:

\[
\begin{array}{c}
\mathbb{Z}(B\pi \times B\pi)_* \xrightarrow{\phi \times \phi} \mathbb{Z}(BG \times BG)_* \\
\mathbb{Z}B\pi \xrightarrow{i} \mathbb{Z}(B\pi \times B\pi)_* \xrightarrow{\phi \times \phi} \mathbb{Z}(BG \times BG)_* \xrightarrow{f} \mathbb{Z}Bm(G)_* \\
\mathbb{Z}B\pi \xrightarrow{D} \mathbb{Z}(B\pi \times B\pi)_* \xrightarrow{\phi \times \phi} \mathbb{Z}(BG \times BG)_* \xrightarrow{f} \mathbb{Z}Bm(G)_* \\
\end{array}
\]

It commutes since it is obtained from a commutative diagram of group homomorphisms.

For $g \in m(G)$, let $S_g := S_{m(G),g}$: id $\simeq \mu_g$ be the chain homotopy in Theorem 4.7 Then we obtain a chain homotopy

\[
S_g f(\phi \times \phi)i: f(\phi \times \phi)i \simeq \mu_g f(\phi \times \phi)i = f(\phi \times \phi)j
\]

by Lemma 4.1 (2). Similarly we obtain a chain homotopy

\[
S_t f(\phi \times \phi)i: f(\phi \times \phi)i \simeq f(\phi \times \phi)D.
\]

Since $Q: e \simeq \phi$, Lemma 5.4 gives us a partial chain homotopy

\[
T: (\phi \times e - e \times e) + (e \times \phi - e \times e) \simeq \phi \times \phi - e \times e
\]

in dimension $\leq n$. From this we obtain a partial chain homotopy

\[
fTD: f(\phi \times e + e \times \phi - e \times e)D \simeq f(\phi \times \phi)D
\]

in dimension $\leq n$, by Lemma 4.1 (2). Since

\[
f(\phi \times e)D = f(\phi \times \phi)i, \quad f(e \times \phi)D = f(\phi \times \phi)j, \quad f(e \times e)D = e,
\]

it follows that $fTD$ is indeed a chain homotopy

\[
fTD: f(\phi \times \phi)i + f(\phi \times \phi)j - e \simeq f(\phi \times \phi)D.
\]

Now we have

\[
k_G \circ \phi - e = f(\phi \times \phi)i - e \simeq f(\phi \times \phi)D - f(\phi \times \phi)j \quad \text{by (5.8)}
\]

\[
\simeq f(\phi \times \phi)i - f(\phi \times \phi)j \quad \text{by (5.7)}
\]

\[
\simeq f(\phi \times \phi)j - f(\phi \times \phi)j = 0 \quad \text{by (5.6)}.
\]

Also, Lemma 4.1 (1) tells us that

\[
R := fTD - S^t f(\phi \times \phi)i + S^n f(\phi \times \phi)i
\]

is a chain homotopy $R: e \simeq k_G \circ \phi$. Since $Q_0 = 0$ by the hypothesis, we have $T_0 = 0$ by Lemma 5.4. From this it follows that $R_0 = 0$, that is, $d_R(0) = 0$. Also, by Lemma 4.1 (1) and by the estimates in Theorem 4.7 and Lemma 5.4 we obtain

\[
d_R(k) \leq d_{S^t}(k) + d_{S^n}(k) + d_T(k)
\]

\[
\leq 2(k + 1) + 2 \cdot \delta_{E\pi}(k) + (k - 1) \left( \frac{k}{|k/2|} \right) \cdot d_Q(k - 1) \quad \text{for } k \geq 1. \quad \square
\]

Applying Theorem 5.6 repeatedly, we obtain the following result for $i^*_0: G \to \mathbb{A}^n(G)$. 

Definition 5.7. Let \( \delta_{BDH} : \{0, \ldots, n\} \to \mathbb{Z}_{\geq 0} \) be the function defined inductively by the initial condition \( \delta_{BDH}(0) = 0 \) and the recurrence relation
\[
\delta_{BDH}(k) = 2(k + 1) + 2 \cdot \delta_{EZ}(k) + (k - 1) \left( k \left\lfloor \frac{k}{2} \right\rfloor \right) \cdot \delta_{BDH}(k - 1)
\]
for \( k \geq 1 \).

Corollary 5.8. For each integer \( n \geq 0 \), there is a family
\[
\{ \Phi^n_G : e \simeq i^n_G | G \text{ is a group} \}
\]
of partial chain homotopies in dimension \( \leq n \) between \( e, i^n_G : ZBG_* \to ZBA^n(G)_* \), which is uniformly controlled by \( \delta_{BDH} \).

Proof. For \( n = 0 \), the zero map \( \Phi_G := 0 \) is a partial chain homotopy \( \Phi_G : e \simeq \text{id}_G = i^n_G \) in dimension \( \leq 0 \). So the claimed conclusion holds.

Suppose the conclusion for \( n - 1 \) holds. Applying Theorem 5.6 to \( \phi := i^{n-1}_G : G \to \mathbb{A}^{n-1}(G) \) and \( Q := \Phi^{n-1}_G : e \simeq i^{n-1}_G \), it follows that there is a partial chain homotopy
\[
\Phi^n_G : e \simeq k_{n-1} \circ i^{n-1}_G = i^n_G
\]
in dimension \( \leq n \) which satisfies \( d\Phi^n_G(0) = 0 \) and
\[
d\Phi^n_G(k) \leq 2(k + 1) + 2 \cdot \delta_{EZ}(k) + (k - 1) \left( k \left\lfloor \frac{k}{2} \right\rfloor \right) \cdot d\Phi^{n-1}_G(k - 1) \quad \text{for} \quad k \geq 1.
\]
Since \( \{ \Phi^{n-1}_G \} \) is uniformly controlled by \( \delta_{BDH} \), the conclusion for \( n \) follows. \( \Box \)

Now we are ready to complete the proof of Theorem 5.2 stated in the beginning of this section.

Proof of Theorem 5.2. The existence of the desired uniformly controlled family of chain homotopies in Theorem 5.2 is no more than Corollary 5.8. For \( k \leq 4 \), the values of \( \delta_{BDH}(k) \) are obtained by an inductive straightforward computation, using Definition 5.7 and the values of \( \delta_{EZ}(k) \) given in Theorem 4.4. \( \Box \)

6. Explicit universal bounds from presentations of 3-manifolds

In this section we obtain explicit estimates of the Cheeger-Gromov universal bound from fundamental presentations of 3-manifolds.

6.1. Universal bounds from triangulations

The goal of this subsection is to give a proof of Theorem 1.5: suppose \( M \) is a 3-manifold with simplicial complexity \( n \). Then for any \( \phi : \pi_1(M) \to G \),
\[
|\rho^{(2)}(M, \phi)| \leq 363090 \cdot n.
\]

Recall that the simplicial complexity of a 3-manifold \( M \) is the minimal number of 3-simplices in a triangulation (i.e., a simplicial complex structure) of \( M \).

In the proof, we will use the results developed in Sections 3, 4, and 5, as well as the idea of the existence proof of Theorem 1.3 given in Section 2. First we state a corollary of Theorem 5.7 and Corollary 5.8. Recall that we defined the functorial embedding \( i^n_G : G \to \mathbb{A}^n(G) \) in Definition 5.1.
Theorem 6.1. Suppose $M$ is a 3-manifold with simplicial complexity $n$. View $M$ as a manifold over $\mathbb{H}^3(\pi_1(M))$ via the embedding $i^3_1: \pi_1(M) \to \mathbb{H}^3(\pi_1(M))$. Then there is a smooth bordism $W$ over $\mathbb{H}^3(\pi_1(M))$ between $M$ and a trivial end, whose 2-handle complexity is at most $181545 \cdot d(\zeta_M)$.

In the proof of Theorem 6.1 given below, there is a small technicality which arises from that we use two chain complexes for a simplicial set $X$: the cellular chain complex $C_\ast(X)$ of its geometric realization, which was used in Section 3 and the Moore complex $\mathbb{Z}X_\ast$ associated to $X$, which was used in Sections 4 and 5. It is known that if we denote by $D_\ast(X)$ the subgroup of $\mathbb{Z}X_\ast$ generated by degenerate simplices of $X$, then $D_\ast(X)$ is indeed a subcomplex, $C_\ast(X) \cong \mathbb{Z}X_\ast/D_\ast(X)$, and the projection $p: \mathbb{Z}X_\ast \to C_\ast(X)$ is a chain homotopy equivalence [ML95, p. 236]. See the appendix [2] for more details.

Proof of Theorem 6.1. For convenience, we write $\pi := \pi_1(M)$, $\Gamma := \mathbb{H}^3(\pi_1(M))$, and $i := i^3_1: \pi \to \Gamma$. Choose a simplicial complex structure of $M$ with minimal number of 3-simplices. As abuse of notation, we denote by $M$ the simplicial set obtained from this simplicial complex structure. As before, let $\zeta_M \in C_3(M)$ be the sum of oriented 3-simplices of $M$ that represents the fundamental class $[M] \in H_3(M)$. Since $M$ is a simplicial complex, $C_\ast(X)$ is a subcomplex of $\mathbb{Z}_\ast X$, and the projection $p: \mathbb{Z}X_\ast \to C_\ast(X)$ is a left inverse of the inclusion. In particular $\zeta_M$ lifts to a cycle $\xi_M \in \mathbb{Z}M_3$. We have $d(\xi_M) = d(\zeta_M).

By Theorem 3.7 (see also Proposition 3.1 in the appendix), the identity map $\pi_1(M) \to \pi = \pi_1(B\pi)$ induces a simplicial-cellular map $j: M \to B\pi$. Let $\phi = \iota \circ j: M \to B\pi \to B\Gamma$. By Theorem 5.2, there is a partial chain homotopy $\Phi: e \simeq \iota$ defined in dimension $\leq 3$. (Using our convention, here $e$ and $i$ designates the induced chain maps $\mathbb{Z}B\pi_* \to \mathbb{Z}B\Gamma_*$.)

Since $\xi_M$ is a cycle, we have

\[
\phi(\xi_M) = i(j(\xi_M)) = e(j(\xi_M)) + \Phi(\partial(j(\xi_M))) + \partial(\Phi(j(\xi_M))) = e(j(\xi_M)) + \partial(\Phi(j(\xi_M)))
\]

in $\mathbb{Z}B\Gamma_3$. Note that the image of $e: \mathbb{Z}B\Gamma_1 \to \mathbb{Z}B\Gamma$, lies in $D_1(\Gamma')$ for $i > 0$. By applying the projection $p: \mathbb{Z}B\Gamma_* \to C_\ast(\Gamma')$ to (6.1), it follows that the 4-chain $u := p(\Phi(j(\xi_M)))$ satisfies $\phi_\ast(\zeta_M) = \partial u$ in the cellular chain complex $C_\ast(\Gamma')$. Here we use that $p \circ \phi = \phi \circ p$ for a morphism $\phi$ of simplicial sets.

Theorem 5.2 also tells us that $d_\phi(3) \leq \delta_{BDH}(3) = 186$. We have $d_j(k) = d_\phi(k) = 1$ since $j$ is (induced by) a simplicial map and $p$ is a projection sending a basis element to a basis element or zero. From this it follows that

\[
d(u) = d(p(\Phi(j(\xi_M)))) \leq d_\phi(3) \cdot d_j(3) \cdot d(\xi_M) = 186 \cdot d(\zeta_M).
\]

Now we apply Theorem 6.9 to $(M, \phi, u)$. This gives us a smooth bordism $W$ over $\Gamma$ between $M$ and another 3-manifold $N$ which is trivially over $B\Gamma$, where

\[
(2\text{-handle complexity of } W) \leq 195 \cdot d(\zeta_M) + 975 \cdot d(u) \leq 181545 \cdot d(\zeta_M). \quad \square
\]

Proof of Theorem 1.5. Suppose $M$ is a closed 3-manifold with simplicial complexity $n$, and $\phi: \pi_1(M) \to G$ is a homomorphism. By Theorem 6.1, there is a smooth bordism $W$ with $\partial W = M \sqcup -N$ over $\mathbb{H}^3(\pi_1(M))$, where $N$ is trivially over $\mathbb{H}^3(\pi_1(M))$ and the 2-handle complexity of $W$ is at most $181545 \cdot n$. Let $\Gamma := \mathbb{H}^3(G)$. Similarly to the proof
of Theorem 1.3, we consider the following commutative diagram:

\[
\begin{array}{ccc}
\pi_1(M) & \xrightarrow{\phi} & G \\
\downarrow^\pi & & \downarrow^\pi \\
\pi_1(W) & & \end{array}
\]

\[\xymatrix{ & \mathbb{A}^3(\pi_1(M)) \ar[dl]_{\pi_3^2(\pi_1(M))} \ar[dr]^{\pi_3^2(G)} \\
\mathbb{A}^3(\pi_1(W)) \ar[ur]^{\mathbb{A}(\phi)} & & G}
\]

By \(L^2\)-induction and Remark 3.3, we can compute the \(\rho\)-invariant as the \(L^2\)-signature defect of \(W\) as follows:

\[
\rho^{(2)}(M, \phi) = \rho^{(2)}(M, \pi_3 \circ \phi) = \text{sign}^{(2)}_\Gamma W - \text{sign} W.
\]

Since both \(|\text{sign}^{(2)}_\Gamma W|\) and \(|\text{sign} W|\) are not greater than the 2-handle complexity of \(W\), it follows that

\[
|\rho^{(2)}(M, \phi)| \leq 2 \cdot 181545 \cdot n = 363090 \cdot n.
\]

\[\square\]

6.2. Universal bounds from surgery presentations

Recall that \(c(L)\) denotes the crossing number of a link \(L\). Also recall that for a framed link \(L\), we define \(f(L) = \sum_i |n_i|\) where \(n_i \in \mathbb{Z}\) is the framing on the \(i\)th component of \(L\).

In this subsection we prove Theorem 1.9, which says: suppose \(M\) is a 3-manifold obtained by surgery along a framed link \(L\) in \(S^3\). Then

\[
|\rho^{(2)}(M, \phi)| \leq 69713280 \cdot c(L) + 34856640 \cdot f(L)
\]

for any homomorphism \(\phi: \pi_1(M) \to G\) into any group \(G\).

We first state a triangulation result for surgery manifolds of links.

**Lemma 6.2.** Suppose \(D\) is a planar diagram of a link \(L\) with \(c\) crossings, in which each component is involved in a crossing. Let \(M\) be the 3-manifold obtained by surgery on \(L\) along the blackboard framing of \(D\). Then \(M\) has simplicial complexity at most \(96c\).

Before proving lemma 6.2, we discuss its consequences. First, from Lemma 6.2 and Theorem 1.5, we immediately obtain the following statement.

**Theorem 6.3.** Suppose \(M\) is as in Lemma 6.2. Then

\[
|\rho^{(2)}(M, \phi)| \leq 34856640 \cdot c
\]

for any homomorphism \(\phi: \pi_1(M) \to G\).

**Example 6.4.** Consider the Stevedore knot, which is \(6_1\) in the table in Rolfsen [Rol76], or KnotInfo [CL]. It is the simplest nontrivial ribbon knot. It has a planar diagram with 6 crossings, where 2 of them have the same sign but the other 4 have the opposite sign. Applying Reidemeister move I twice, we obtain a planar diagram with 8 crossings and writhe zero. Since the blackboard framing is the zero framing for this diagram, it follows that the zero surgery manifold \(M\) of \(6_1\) satisfies \(|\rho^{(2)}(M, \phi)| \leq 34856640 \cdot 8 = 278853120\) for any \(\phi\), by Theorem 6.3. The universal bound is less than .3 billion!

The argument of Example 6.4 generalizes to the following observation, which tells us how to reduce a general integral coefficient surgery to the special case of Lemma 6.2. We say that a component of a link in \(S^3\) is split if there is an embedded 3-ball in \(S^3\) which contains the component and is disjoint to other components.
Lemma 6.5. Suppose $L$ is a framed link in $S^3$. Then there is a planar diagram with $2c(L) + f(L)$ or less crossings such that the blackboard framing agrees with the given framing of $L$. Furthermore, a component of $L$ is involved in a crossing unless it is a split unknotted zero framed component.

Proof. Choose a minimal planar diagram on $S^2$ for $L$, which has $c(L)$ crossings. Let $K_i$ be the $i$th component. Let $w_i$ be the writhe of $K_i$ (forgetting other components), that is, the blackboard framing on $K_i$ is $w_i \in \mathbb{Z}$. Since a crossing contributes 1, 0, or $-1$ to $w_i$ for some $i$, it follows that $|w_1| + \cdots + |w_i| \leq c(L)$. Observe that if we add a local kink by Reidemeister move I, then the blackboard framing changes by $\pm 1$. As before, let $n_i \in \mathbb{Z}$ be the given framing on $K_i$. By adding $n_i - w_i$ local kinks to $K_i$, we obtain a new diagram, say $D$, for which the blackboard framing agrees with the framing $n_i$ on each component. The number of crossings of $D$ is at most

$$c(L) + |w_1| + \cdots + |w_i| + |n_1| + \cdots + |n_i| \leq 2c(L) + f(L).$$

Since we have added $n_i - w_i$ local kinks to $K_i$, it follows that $K_i$ is involved in no crossings only if $K_i$ is an embedded circle in the planar diagram which is disjoint from other components and $n_i = w_i = 0$. Such a component is split, unknotted, and zero framed. \qed

The following is an immediate consequence of Lemmas 6.2 and 6.5:

Lemma 6.6. If $M$ is obtained by surgery on a framed link $L$ in $S^3$ and has no split unknotted zero framed component, then the simplicial complexity of $M$ is at most $128 \cdot c(L) + 96 \cdot f(L)$.

Proof of Theorem 1.8. Suppose $L$ is a given framed link in $S^3$. We claim that we may assume that $L$ does not have any split unknotted zero framed component. Suppose $L$ has $k$ split unknotted zero framed components, and let $L'$ be the sublink consisting of the other components. Let $M$ and $M'$ be the 3-manifolds obtained by surgery on $L$ and $L'$, respectively. Then $M'$ is the connected sum of $M'$ and $k$ copies of $S^1 \times S^2$. Since $S^3 \times S^2 = \partial(S^1 \times D^4) \times \pi_1(S^1 \times S^2) = \mathbb{Z}$ and $S^3 \times D^3$ has no 2-handles, $\rho(2)(S^1 \times S^2) \psi = 0$ for any $\psi$. Since $\rho(2)$ is additive under connected sum, we have $\rho(2)(M, \phi) = \rho(2)(M', \phi')$ where $\phi' = \pi_1(M') \rightarrow G$ is the homomorphism induced by $\phi = \pi_1(M) \rightarrow G$. Since we are interested in a universal bound, it follows that we may assume $L = L'$ as claimed.

By the claim and by Lemma 6.6 it follows that the surgery manifold $M$ has simplicial complexity at most $192 \cdot c(L) + 96 \cdot f(L)$. By Theorem 1.5 it follows that

$$|\rho(2)(M, \phi)| \leq 69713280 \cdot c(L) + 34856640 \cdot f(L)$$

for any homomorphism $\phi : \pi_1(M) \rightarrow G$. \qed

Proof of Lemma 6.2. We will construct a triangulation of the exterior of $L$ which is motivated from J. Weeks’ SnapPea, and then will triangulate the Dehn filling tori in a compatible way.

Consider the dual graph $G$ of $D$, whose regions are quadrangles corresponding to crossings, as illustrated in the left of Figure 9. View the link $L$ as a submanifold of $S^2 \times [-1, 1]$, and remove from $S^2 \times [-1, 1]$ an open tubular neighborhood $\nu(L)$ of $L$ which is tangential to $S^2 \times \{-1, 1\}$ at (each crossing) $\times \{-1, 1\}$; cutting along $G \times [-1, 1]$, we obtain pieces corresponding to the crossings of $D$, as shown in the middle of Figure 8.

Cutting each piece along $D \times [-1, 1]$, we obtain 4 equivalent subpieces; a subpiece is shown in the right of Figure 8. The hatched regions represent $\partial \nu(L)$. Each subpiece can be viewed as a cube shown in Figure 9. Let $p$ be the vertex shown in the left of Figure 9 and triangulate the three faces not adjacent to $p$ as in the right of Figure 9. By taking a
cone from $p$, we obtain a triangulation of the cubic subpiece. Since the triangulation of the faces away from $p$ has 14 triangles, the subpiece triangulation has 14 tetrahedra. By applying this to each subpiece, we obtain a triangulation of $S^2 \times [-1, 1] \setminus \nu(L)$, which has $14 \cdot 4c = 56c$ tetrahedra.

For $t = -1, 1$, the triangulation restricts to a triangulation of $S^2 \times \{t\}$ with $8c$ triangles. Attaching two 3-balls triangulated as the cone of these triangulations, we obtain a triangulation of $S^3 \setminus \nu(L)$ which has $56c + 2 \cdot 8c = 72c$ tetrahedra.

In our triangulation, the $8c$ hatched quadrangular regions are paired up to form $4c$ annuli, and a boundary component of $\nu(L)$ is a union of $4k$ such annuli, where $k$ is the number of times the corresponding component of $L$ passes through a crossing. (Since a component may pass through the same crossing twice, $k$ may not be the number of crossings that the component passes through.) See the left of Figure 10; the hatched meridional annulus is one of these $4k$ annuli. Also, the circle $\alpha$ in the left of Figure 10 is the union of the top edges of the hatched quadrangles in Figure 9. Obviously $\alpha$ is a longitude of $L$ taken along the blackboard framing, along which we perform surgery. Similarly, the bottom edges of the hatched quadrangles form a parallel of $\alpha$, which we denote by $\alpha'$.

Let $r$ be the number of the components of $L$, and take $r$ copies of the solid torus $D^2 \times S^1$. Attach them to the exterior $S^3 \setminus \nu(L)$ along orientation reversing homeomorphisms of boundary tori which takes the curves $\alpha$ and $\alpha'$ to meridians bounding disks and takes
Figure 10. A boundary component and a Dehn filling torus.

our hatched annulus to a longitudinal annulus, as shown in Figure 10. Pulling back the triangulation of $\partial (S^3 \setminus \nu (L))$, we obtain a triangulation of $\partial (D^2 \times S^1)$. It extends to a triangulation of $D^2 \times S^1$ as follows. By cutting the $D^2 \times S^1$ along the meridional disks bounded by $\alpha$ and $\alpha'$, we obtain two solid cylinders $D^2 \times [0, 1]$. Note that we already have $4k$ vertices on $\partial D^2_0$. We triangulate $D^2_0$ into $4k$ triangles, by drawing lines joining the vertices to the center of $D^2_0$. See the bottom picture in Figure 10. Taking the product with $[0, 1]$, we decompose $D^2 \times [0, 1]$ into $4k$ triangular prisms. Note that each hatched quadrangle gives one prism. Finally we apply the prism decomposition (Figure 2) to each prism. Since each prism gives 3 tetrahedra and there are $8c$ hatched quadrangles, the union of all the Dehn filling solid tori is decomposed into $24c$ tetrahedra.

The triangulation of our surgery manifold $M$ is obtained by adjoining the Dehn filling tori triangulation to that of the exterior. By the above tetrahedra counting, it follows that the number of tetrahedra in $M$ is at most $72c + 24c = 96c$.

6.3. Universal bounds from Heegaard splittings and mapping classes

Recall from Definition 1.7 that the Heegaard-Lickorish complexity of a closed 3-manifold $M$ is the minimal word length, in the Lickorish generators, of a mapping class which gives a Heegaard splitting of $M$. Here the Lickorish generators of the mapping class group $\text{Mod}(\Sigma_g)$ of an oriented surface $\Sigma_g$ of genus $g$ are defined to be the $\pm 1$ Dehn twists along the curves $\alpha_1, \ldots, \alpha_g, \beta_1, \ldots, \beta_g, \gamma_1, \ldots, \gamma_{g-1}$ shown in Figure 1.

To make it precise, we fix conventions for Heegaard splitting. We fix a standard embedding of $\Sigma_g$ into $S^3$ as in Figure 1. Then $\Sigma_g$ bounds the inner handlebody $H_1$ and the outer handlebody $H_2$ in $S^3$. Let $i_j: \Sigma_g \to H_j$ ($j = 1, 2$) be the inclusion. The mapping class $h \in \text{Mod}(\Sigma_g)$ of a homeomorphism $f: \Sigma_g \to \Sigma_g$ gives a Heegaard splitting $(\Sigma_g, \{\beta_i\}, \{f(\alpha_i)\})$ of the 3-manifold

$$M = (H_1 \cup H_2)/i_1(f(x)) \sim i_2(x), \ x \in \Sigma_g.$$  

In other words, $M$ is obtained by attaching $g$ 2-handles to $H_1$ along the curves $f(\alpha_i)$ and then attaching a 3-handle. Under our convention, the identity mapping class gives us $S^3$.

In this section we give a proof of Theorem 1.8 if $M$ is a closed 3-manifold with Lickorish-Heegaard complexity $\ell$, then for any homomorphism $\phi: \pi_1(M) \to G$,

$$|\rho(2)(M, \phi)| \leq 251258280 \cdot \ell.$$
We begin with an observation on the Heegaard genus and the Heegaard-Lickorish complexity.

**Lemma 6.7.** Suppose $M$ is a closed 3-manifold with a Heegaard splitting given by a mapping class $h \in \text{Mod}(\Sigma_g)$ which is a product of $\ell$ Lickorish generators. Then for some $g' \leq 2\ell$, $M$ admits a Heegaard splitting given by a mapping class $h' \in \text{Mod}(\Sigma_{g'})$ which is a product of $\ell$ Lickorish generators.

*Proof.* For a Lickorish generator $t \in \text{Mod}(\Sigma_g)$, we say that $t$ passes through the $i$th hole of $\Sigma_g$ if $t$ is a Dehn twist along either $\alpha_i$, $\beta_i$, $\gamma_i$ or $\gamma_i - 1$ (see Figure 1). It is easily seen from Figure 1 that a Lickorish generator can pass through at most two holes of $\Sigma_g$. Therefore, the Lickorish generators which appear in the given word expression of $h$ can pass through at most $2\ell$ holes. If $g > 2\ell$, then for some $i$, no Lickorish generator used in $h$ passes through the $i$th hole. By a destabilization which removes the $i$th hole from $\Sigma_g$, we obtain a Heegaard splitting of $M$ of genus $g - 1$ given by a mapping class which a product of $\ell$ Lickorish generators. By repeating this, the proof is completed. □

**Lemma 6.8.** Suppose a closed 3-manifold $M$ has Heegaard-Lickorish complexity $\ell$. Then the simplicial complexity of $M$ is at most $692\ell$.

*Proof.* Suppose $h$ gives a Heegaard splitting of a given 3-manifold $M$, and suppose $h$ is a product of $\ell$ Lickorish generators. In [Lic62], Lickorish showed that $M$ is obtained by surgery on an $\ell$-component link $L_0$ in $S^3$, where each component has either $(+1)$ or $(-1)$-framing. His proof tells us more about $L_0$ (another useful reference for this is [Rol76, Chapter 9, Section I]). In fact, $L_0$ lies in a bicollar $\Sigma_g \times [-1, 1]$ in $S^3$, and each component is of the form $\alpha_i \times \{t\}$, $\beta_i \times \{t\}$, or $\gamma_i \times \{t\}$ for some $i$ and $t \in [-1, 1]$. An example is shown in Figure 11. By adding a local kink to each $\alpha_i$, $\beta_i$, $\gamma_i$ on $\Sigma_g$ and by taking their union, we obtain a graph $D$ embedded in $\Sigma_g$, which is shown in Figure 12. We regard the embedded curves $\alpha_i$, $\beta_i$, $\gamma_i$ as subsets of $D$.

Note that for a link in the bicollar $\Sigma_g \times [-1, 1]$, if each component is regular with respect to the projection of $\Sigma_g \times [-1, 1] \to \Sigma_g$, then the blackboard framing with respect to $\Sigma_g$ is well-defined; the preferred parallel with respect to the blackboard framing is defined to be the push-off along the $[-1, 1]$ direction. In particular, for our surgery link $L_0$, the blackboard framing with respect to $\Sigma_g$ is the zero framing. We apply Reidemeister move I to each component of $L_0$ to obtain a new link $L$ which lies in $D \times [-1, 1] \subset \Sigma \times [-1, 1] \subset S^3$ and whose blackboard framing is the desired $(\pm 1)$-framing for surgery; see Figure 13 for an example.
Now, in order to construct a triangulation of $\Sigma_g \times [-1,1] \setminus \nu(L)$, we proceed similarly to the proof of Lemma 6.2; the difference is that we now use a “link diagram” on $\Sigma_g$, instead of a planar diagram. Let $G$ be the dual graph of $D$ on $\Sigma_g$. Each face of $G$ is a quadrangle. Cutting $\Sigma_g \times [-1,1] \setminus \nu(L)$ along $G \times [-1,1]$, we obtain cubic pieces with tubes removed, as shown in the left of Figure 14. Cutting along $D \times [-1,1]$, each piece is divided into 4 subpieces; see the middle of Figure 14.

We triangulate the three front faces of each subpiece as in the right of Figure 14 and then triangulate the subpiece by taking a cone at the opposite vertex, as we did in the proof.
We claim that there are $6k + 6$ tetrahedra in this triangulation, where $k$ is the number of hatched quadrangles in the right of Figure 13. The number of tetrahedra in the subpiece is equal to the number of triangles in the three front faces. There are two triangles in the top face. To count triangles in the remaining two faces, observe that the front middle vertical edge is divided into $2k + 1$ 1-simplices. There are $4k + 2$ triangles that have one of these 1-simplices as an edge, and there are $2k + 2$ remaining triangles. Therefore there are total $6k + 6$ triangles, as we claimed.

Collecting the triangulations of the subpieces, we obtain a triangulation of $\Sigma_g \times [-1, 1] \setminus \nu(L)$. To estimate the number of tetrahedra, first observe that the graph $D$ has $6g − 3$ vertices, where $g$ is the genus of the Heegaard surface $\Sigma_g$. Therefore its dual graph $G$ has $6g − 3$ faces, and since each face of $G$ gives us 4 subpieces of $\Sigma_g \times [-1, 1] \setminus \nu(L)$, we have total $24g − 12$ subpieces. Also, observe that a component of $L$ is cut into at most 5 pieces by $G$, and so can contribute at most 20 hatched quadrangles. It follows that there are at most

$$6 \cdot 20\ell + 6 \cdot (24g − 12) = 120\ell + 144g − 72$$

tetrahedra in our triangulation of $\Sigma_g \times [-1, 1] \setminus \nu(L)$.

Now we triangulate the inner and outer handlebodies which are obtained by cutting $S^3$ along $\Sigma_g \times [0, 1]$. Let $D_1, \ldots, D_g$ be disjoint disks in the outer handlebody bounded by the curves $\alpha_i$ in Figure 14, and $D'_1, \ldots, D'_g$ be disjoint disks in the inner handlebody bounded by the curves $\beta_i$. Our triangulation on $\Sigma \times \{±1\}$ divides each of $\partial D_1$ and $\partial D_g$ into six 1-simplices, $D_i (i = 2, \ldots, g − 1)$ into eight 1-simplices, and $\partial D'_i$ into four 1-simplices. Extending this, we triangulate each of $D_1, D_g$ into 4 triangles, $D_i (i = 2, \ldots, g − 1)$ into 6 triangles, and each $D'_i$ into 2 triangles by drawing arcs joining vertices. Cutting the handlebodies along the disks $D_i$ and $D'_i$, we obtain two 3-balls. The triangulations of $\Sigma_g \times 1$ and $D_i$ give us a triangulation of boundary of the outer 3-ball. Recall that the top face of each subpiece we considered above consists of two triangles, and there are $24g − 12$ subpieces. Therefore the boundary of the outer 3-ball has at most $2(24g − 12) + 2(6g − 4) = 60g − 32$ triangles. Taking a cone at the center, the outer 3-ball is triangulated into at most $60g − 32$ tetrahedra. Similarly the inner 3-ball is triangulated into $2(24g − 12) + 2 \cdot 2g = 52g − 24$ tetrahedra.

We triangulate the Dehn filling tori as in Lemma 6.3. Since there are at most $20\ell$ hatched quadrangles and each hatched quadrangle contributes at most 3 tetrahedra (= one triangular prism) in the Dehn filling tori, there are at most $60\ell$ tetrahedra in the Dehn filling tori.

It follows that our triangulation of the surgery manifold $M$ has at most

$$(120\ell + 144g − 72) + (60g − 32) + (52g − 24) + 60\ell = 180\ell + 256g − 128$$

tetrahedra. By Lemma 6.7 we may assume that $g \leq 2\ell$. It follows that the simplicial complexity of $M$ is at most $692\ell$. \hfill \Box

Proof of Theorem 1.8 Suppose $M$ has Heegaard-Lickorish complexity $\ell$. Then $M$ has simplicial complexity $\leq 692\ell$ by Lemma 6.7. By Theorem 1.5 it follows that

$$|\rho^{(2)}(M, \phi)| \leq 251258280 \cdot \ell$$

for any homomorphism $\phi$ of $\pi_1(M)$. \hfill \Box
7. Complexity of 3-manifolds

In this section, we present applications of our Cheeger-Gromov bounds to the study of the complexity of 3-manifolds. We will first introduce a method to compute the Cheeger-Gromov invariant over a finite cyclic group. Using our universal bound results together with this computation, we will find new lower bounds of the complexity of lens spaces. We will also show that the Cheeger-Gromov bounds in Theorems 1.5, 1.8, and 1.9 and the 2-handle complexity of the 4-dimensional bordism in Theorem 5.9 are asymptotically optimal.

7.1. Computing Cheeger-Gromov invariants over finite cyclic groups

If \( \phi \) is a homomorphism of \( \pi_1(M) \) onto a finite cyclic group, then the Cheeger-Gromov invariant \( \rho^{(2)}(M, \phi) \) can be obtained from an invariant of Atiyah and Singer in [AS68], which is essentially equivalent to the Casson-Gordon invariant in [CG78]. For this case, in Theorem 7.1 stated and proven below, we give an explicit formula for \( \rho^{(2)}(M, \phi) \). Our proof depends on results of Casson-Gordon [CG78] and Gilmer [Gil81], which in turn can be shown using the Atiyah-Singer G-signature theorem.

Recall that for an oriented link \( L \) in \( S^3 \), a Seifert matrix \( A \) is defined by choosing a Seifert surface \( F \) (which may or may not connected) and a basis of \( H_1(F) \). The Levine-Tristram signature function of \( L \) is defined by

\[
\sigma_L(\omega) = \text{sign} \left( (1 - \omega)A + (1 - \overline{\omega})A^T \right), \quad \omega \in S^1 \subset \mathbb{C}.
\]

Suppose \( K \) is an oriented knot in \( S^3 \) and \( n \) and \( r \) are integers. We call a union of finitely many disjoint parallels of \( K \) an \( n \)-twisted \( r \)-cable if each parallel is of linking number \( n \) with \( K \) and oriented in such a way that the sum of the parallels is homologous to \( rK \) in a tubular neighborhood of \( K \).

**Theorem 7.1.** Suppose \( M \) is a closed 3-manifold, and \( L = K_1 \sqcup \cdots \sqcup K_r \) is an \( r \)-component oriented link in \( S^3 \) such that surgery on \( L \) with integral coefficients \( n_1, \ldots, n_r \) gives \( M \). Let \( \Delta = (n_{ij}) \) be the linking matrix defined by \( n_{ij} = n_i \) and \( n_{ij} = \text{lk}(K_i, K_j) \) for \( i \neq j \). Suppose \( \phi : \pi_1(M) \to \mathbb{Z}_d \) is a homomorphism. Let \( \mu_i \) be the positive meridian of \( K_i \), and let \( r_i \) be an integer satisfying \( r_i = \phi(\mu_i) \) in \( \mathbb{Z}_d \). Let \( L' \) be the link obtained from \( L \) by replacing each component \( K_i \) with a nonempty \( n_i \)-twisted \( r_i \)-cable of \( K_i \). Then we have

\[
\rho^{(2)}(M, \phi) = \frac{1}{d} \sum_{k=1}^{d-1} \sigma_L(\epsilon^{2\pi k \sqrt{-1}/d}) - \frac{d-1}{d} \text{sign} \Lambda + \frac{d^2 - 1}{3d^2} \sum_{i,j} r_i r_j n_{ij}.
\]

**Proof.** In [CG86], Casson and Gordon defined an invariant \( \sigma_{t}(M, \phi) \) as follows. Since \( \Omega_3(\mathbb{Z}_d) \) is finite, there is a 4-manifold \( W \) over \( \mathbb{Z}_d \) such that \( \partial W = sM \) over \( \mathbb{Z}_d \) for some integer \( s \neq 0 \). Let \( \tilde{W} \) be the \( \mathbb{Z}_d \)-cover of \( W \). The generator \( 1 \in \mathbb{Z}_d \) induces an order \( d \) linear operator \( g : H_2(\tilde{W}; \mathbb{C}) \to H_2(\tilde{W}; \mathbb{C}) \). Let \( \sigma_k(\tilde{W}) \) be the signature of the intersection form of \( \tilde{W} \) restricted on the \( \epsilon^{2\pi k \sqrt{-1}/d} \)-eigenspace of \( g \). Then the rational number

\[
\sigma_k(M, \phi) := \frac{1}{s} \left( \sigma_k(\tilde{W}) - \text{sign}(W) \right)
\]

is well-defined, independent of the choice of \( W \). (Our sign convention is opposite of that of [CG86] but agrees with that of [Gil81].) It is known that \( \sigma_0(M, \phi) = 0 \); e.g., see [CG86 p. 40]. Due to Gilmer [Gil81] Theorem 3.6], we have

\[
\sigma_k(M, \phi) = \sigma_{L'}(\epsilon^{2\pi k \sqrt{-1}/d}) - \text{sign} \Lambda + \frac{2(d-k)k}{d} \sum_{i,j} r_i r_j n_{ij}.
\]
for $0 < k < d$. See also [CG78, Section 3] for a special case.

It is related to $\rho^{(2)}(M, \phi)$ as follows. Since $\mathbb{Z}_d$ is finite, the group von Neumann algebra $\mathcal{N}\mathbb{Z}_d$ is equal to the ordinary group ring $\mathbb{C}[\mathbb{Z}_d]$ and the $L^2$-dimension is given by $\dim Z_d^{(2)} = \frac{1}{d} \dim \mathbb{C}$. Since $H_2(W; \mathbb{C}[\mathbb{Z}_d]) \cong H_2(W; \mathbb{C})$ is the orthogonal sum of the $e^{2\pi k \sqrt{-1}/d}$ eigenspaces, $k = 0, \ldots, d - 1$, it follows that

$$\text{sign}_{Z_d}^{(2)} W = \frac{1}{d} \sum_{k=0}^{d-1} \sigma_k(W).$$

From this and (7.1), it follows that

$$(7.3) \quad \rho^{(2)}(M, \phi) = \text{sign}_{Z_d}^{(2)} W - \text{sign} W = \frac{1}{d} \sum_{k=0}^{d-1} \sigma_k(M, \phi).$$

Substituting (7.2) into (7.3), we obtain the claimed conclusion. \hfill \Box

### 7.2. Lower bounds of the complexity of knot surgery manifolds

For a knot $K$ in $S^3$, we denote by $g_4(K)$ the (topological) slice genus of $K$. That is, $g_4(K)$ is the minimal genus of a properly embedded locally flat orientable surface in $B^4$ bounded by $K$. Recall that $c(M)$ is the (pseudo-simplicial) complexity of a 3-manifold $M$.

**Theorem 7.2.** Suppose $K$ is a knot in $S^3$, and let $M(K, n)$ be the 3-manifold obtained by $n$-surgery along $K$. Then $c(M(K, n)) \in \Theta(n)$. In fact, we have

$$\frac{|n| - 3 - 6g_4(K)}{627419520} \leq c(M(K, n)) \leq 96|n| + 128c(K).$$

**Remark 7.3.** The slice genus $g_4(K)$ in Theorem 7.2 can be replaced by either the unknotting number $u(K)$, the genus $g(K)$, or the crossing number $c(K)$, since $g_4(K)$ is not greater than any one of them. This gives us lower bounds which are easier to compute.

Applying Theorem 7.2 to the unknot, we immediately obtain the following result:

**Theorem 7.4.** $c(L(n, 1)) \geq \frac{n - 3}{627419520}$ for $n > 3$.

Combining Theorem 7.4 with the result in [JR] that $c(L(n, 1)) \leq n - 3$, we obtain Corollary [1.15] $c(L(n, 1)) \in \Theta(n)$. In fact, for each $n > 3$,

$$\frac{n - 3}{627419520} \leq c(L(n, 1)) \leq n - 3.$$

As a part of the proof of Theorem 7.2, we first compute a Cheeger-Gromov invariant of knot surgery manifolds. We state it as a lemma because we also need it in the next subsection.

**Lemma 7.5.** Suppose $n > 0$, and let $\phi: \pi_1(M(K, n)) \to H_1(M(K, n)) = \mathbb{Z}_n$ be the abelianization. Then

$$\rho^{(2)}(M(K, n), \phi) = \frac{n}{3} + \frac{2}{3n} - 1 + \frac{1}{n} \sum_{k=1}^{n-1} \sigma_k(e^{2\pi k \sqrt{-1}/n}).$$

**Proof.** Note that $\phi$ takes a meridian of $K$ to $1 \in \mathbb{Z}_n$. Also, the $n$-twisted 1-cable of $K$ is $K$ itself, and the linking matrix for the $n$-surgery on $K$ is $\Lambda = [n]$. Therefore, by applying Theorem 7.1 we obtain the desired formula for $\rho^{(2)}(M(K, n), \phi)$.
Proof of Theorem 7.2. We may assume $n > 0$, by taking the mirror image of $K$ if $n < 0$. By Lemma 6.6 and Corollary 1.11, we obtain the lower bound

$$c(M(K, n)) \geq \frac{1}{627419520} \left(n - 3 + \frac{3}{n} \sum_{k=1}^{n-1} \sigma_K(e^{2\pi k \sqrt{-1}/n})\right).$$

It is known that $|\sigma_K(\omega)| \leq 2g_4(K)$ for any root of unity $\omega \in S^1$. From this it follows that

$$\frac{1}{n} \sum_{k=1}^{n-1} |\sigma_K(e^{2\pi k \sqrt{-1}/n})| \leq 2g_4(K).$$

Combining the above two inequalities, we obtain the lower bound stated in Theorem 7.2.

Since $M(K, n)$ is obtained by $n$-surgery on $K$, we have

$$c(M(K, n)) \leq 96n + 128c(K)$$

by Lemma 6.6. □

As discussed below in detail, it turns out that for odd $n$, the lower bound in Theorem 7.4 can be arbitrarily larger than lower bounds from previously known methods. Recall that for two functions $f(n)$ and $g(n)$, we say $g(n)$ is dominated by $f(n)$ and write $g(n) \in o(f(n))$ if $\limsup_{n \to \infty} |g(n)/f(n)| = 0$.

1. Since $L(n, 1)$ is a Seifert fibered space, the lower bound from hyperbolic volume of Matveev-Petronio-Vesnin [MPV01] does not apply to $L(n, 1)$.
2. When $n$ is odd, since $H_1(L(n, 1); \mathbb{Z}_2) = 0$, the methods of Jaco-Rubinstein-Tillman [JRT09, JRT11, JRT13] using double covers and the $\mathbb{Z}_2$-Thurston norm do not give any nonzero lower bound.
3. In [MP01], Matveev and Pervova proved the following:

$$c(M) \geq 2 \log_5 |tH_1(M)| + \text{rank} H_1(M),$$

where $|tH_1(M)|$ denotes the order of the torsion subgroup of $H_1(M)$. For $M = L(n, 1)$, this gives us $c(L(n, 1)) \geq 2 \log_5 n$. This bound is logarithmic, which is dominated by the linear lower bound in Theorem 7.4.
4. In [MP01], they showed that $c(M) \geq c(\pi_1(M))$, where the complexity $c(G)$ of a group $G$ is defined to be the minimal lengths of a finite presentation of $G$. The length of a finite presentation is the sum of the word length of the defining relators. Computation of $c(G)$ is difficult in general; even for $G = \mathbb{Z}_n$, the answer seems complicated. From the presentation $(g \mid g^n)$, we obtain $c(\mathbb{Z}_n) \leq n$. Interestingly, for infinitely many $n$, $c(\mathbb{Z}_n)$ is much smaller than $n$. For instance, let $n = k^2 - 1$. Then $\mathbb{Z}_n$ admits a presentation $(x, y \mid x^k y^{-1}, x^{-1} y^k)$. Since its length is $2(k + 1)$, we have $c(\mathbb{Z}_n) \leq 2(k + 1) = 2(\sqrt{n} + 1 + 1)$. It follows that, for $M = L(n, 1)$ with $n = k^2 - 1$, the lower bound $c(\pi_1(M))$ gives us at best $c(L(n, 1)) \geq 2(\sqrt{n} + 1 + 1)$. This is dominated by the linear lower bound in Theorem 7.4.

From the above observations, Theorem 1.12 in the introduction follows immediately.

Remark 7.6. There are closed 3-manifolds $M$ such that the Cheeger-Gromov invariant $\rho^{(2)}(M, \phi)$, and consequently the lower bound of $c(M)$ given in Corollary 1.11 can be arbitrarily larger than the Thurston norm of any generator of $H^1(M; \mathbb{Z})$. For instance, the computational method in [COT04, Proposition 3.2] tells us how to construct a satellite knot with a fixed genus, say $g$, whose zero-surgery manifold $M$ admits an arbitrarily large value of $\rho^{(2)}(M, \phi)$; the generator of $H^1(M) \cong \mathbb{Z}$ has Thurston norm $\leq 2g - 1$. 
7.3. Linear Cheeger-Gromov bounds are asymptotically optimal

Using the computation in the proof of Theorem 7.2, we can prove Theorem 1.6, which says that the linear Cheeger-Gromov bound in Theorem 1.5 is asymptotically optimal. Recall from the introduction that we define $B_{sc}(n)$ to be the optimal Cheeger-Gromov bound for 3-manifolds with simplicial complexity $n$, that is,

$$B_{sc}(n) = \sup \left\{ |\rho^{(2)}(M, \phi)| \mid M \text{ has simplicial complexity } n \text{ and } \phi \text{ is a homomorphism of } \pi_1(M) \right\}.$$ 

Theorem 1.6 claims that

$$\limsup_{n \to \infty} \frac{B_{sc}(n)}{n} \geq \frac{1}{288},$$

and consequently $B_{sc}(n) \in \Omega(n)$.

Proof of Theorem 1.6. Let $s_n$ be the simplicial complexity of $L(n, 1)$. Since $L(n, 1)$ is obtained by $n$-surgery on a trivial knot, we have

$$\rho^{(2)}(L(n, 1), \text{id}_{\pi_1(L(n, 1))}) = \frac{n}{3} + \frac{2}{3n} - 1$$

by Lemma 7.5. It follows that $B_{sc}(s_n) \geq \frac{1}{3}n - 1$. Also, $s_n \leq 96n$ by Lemma 6.6. It follows that

$$B_{sc}(s_n) \geq \frac{1}{288} - \frac{1}{s_n}$$

for sufficiently large $s_n$. By (7.4) and Theorem 1.5, $s_n \geq (n - 3)/(3 \cdot 363090)$. So $s_n \to \infty$ as $n \to \infty$. It follows that (7.5) holds for infinitely many $s_n$. Taking lim sup of (7.5), the claimed inequality is obtained. □

We can also show that the Cheeger-Gromov bounds in Theorem 1.8 and 1.9 are asymptotically optimal. To state it formally, we use the following definitions.

Definition 7.7. Define

$$B_{HL}(\ell) = \sup \left\{ |\rho^{(2)}(M, \phi)| \mid M \text{ has Heegaard-Lickorish complexity } \ell \text{ and } \phi \text{ is a homomorphism of } \pi_1(M) \right\}.$$ 

Define the surgery complexity of a closed 3-manifold $M$ to be the minimum of $c(L) + f(L)$ over all framed links $L$ in $S^3$ from which $M$ is obtained by surgery. Define

$$B_{surg}(k) = \sup \left\{ |\rho^{(2)}(M, \phi)| \mid M \text{ has surgery complexity } k \text{ and } \phi \text{ is a homomorphism of } \pi_1(M) \right\}.$$ 

Theorems 1.8 and 1.9 tell us that $B_{HL}(\ell) \in \Omega(\ell)$ and $B_{surg}(k) \in \Omega(k)$.

Theorem 7.8. $B_{HL}(\ell) \in \Omega(\ell)$ and $B_{surg}(k) \in \Omega(k)$. In fact,

$$\frac{1}{3} \leq \limsup_{\ell \to \infty} B_{HL}(\ell) \leq 251258280$$

and

$$\frac{1}{3} \leq \limsup_{k \to \infty} B_{surg}(k) \leq 69713280.$$ 

Proof. The upper bounds of lim sup are immediately obtained from Theorems 1.8 and 1.9. The proofs of the lower bounds are identical with that of Theorem 1.6 instead of the fact that the simplicial complexity of $L(n, 1)$ is not greater than $96n$, we use that the Heegaard-Lickorish complexity and the surgery complexity of $L(n, 1)$ are both not greater than $n$. This gives us the lower bound $\frac{1}{3}$ of the lim sup instead of $\frac{1}{396} = \frac{1}{288}$. □
Finally, we show that the 2-handle complexity $195 \cdot d(\zeta_M) + 975 \cdot d(u)$ in Theorem 3.9 is asymptotically best possible. For the reader’s convenience, we recall Theorem 3.9: suppose $M$ is a closed 3-manifold endowed with a triangulation of complexity $d(\zeta_M)$. Suppose $M$ is over $G$ via a simplicial-cellular map $\phi: M \to BG$. If there is a 4-chain $u \in C_4(BG)$ satisfying $\partial u = \phi_#(\zeta_M)$, then there exists a smooth bordism $W$ between $M$ and a trivial end such that 2-handle complexity of $W$ is at most $195 \cdot d(\zeta_M) + 975 \cdot d(u)$. Here $\zeta_M \in C_3(M)$ is the sum of 3-simplices which represents the fundamental class of $M$.

Definition 7.9. Let $M(k)$ be the collection of pairs $(M, \phi)$ of a closed triangulated 3-manifold $M$ and a simplicial-cellular map $\phi: M \to BG$ admitting a 4-chain $u \in C_4(BG)$ such that $\partial u = \phi_#(\zeta_M)$ and $k = d(\zeta_M) + d(u)$. For a given $(M, \phi)$, let $B(M, \phi)$ be the collection of bordisms $W$ over $G$ between $M$ and a trivial end. Define

$$B^{2h}(k) := \sup_{(M, \phi) \in M(k)} \min_{W \in B(M, \phi)} \{\text{2-handle complexity of } W\}.$$ 

Theorem 7.10. $B^{2h}(k) \in O(k) \cap \Omega(k)$. In fact,

$$\frac{1}{107712} \leq \limsup_{k \to \infty} \frac{B^{2h}(k)}{k} \leq 975.$$ 

Proof. Theorem 3.9 tells us that 975 is an upper bound of $B^{2h}(k)/k$ and consequently $c^{2h}(k) \in O(k)$.

To show the rest of the conclusions, we consider the lens space $M = L(n, 1)$. Since $M$ is obtained by the blackboard framing surgery for a planar diagram of the trivial knot with $n$ crossings, there is a triangulation of $M$ of simplicial complexity at most $96n$ by Lemma 6.2. That is, $d(\zeta_M) \leq 96n$. Appealing to Theorem 3.7, choose a simplicial-cellular map $\phi: M \to B\mathbb{Z}/3(\mathbb{Z}_n)$ which induces the inclusion $\pi_1(M) = \mathbb{Z}_n \to \mathbb{Z}/3(\mathbb{Z}_n)$ defined in Definition 5.1. Similarly to the proof of Theorem 6.1 there is a 4-chain $u \in C_4(BG)$ such that $\partial u = \phi_#(\zeta_M)$ and $d(u) \leq 186 d(\zeta_M)$, by Theorem 6.2. Let $k = d(\zeta_M) + d(u)$. By our choice of $k$, $(M, \phi) \in M(k)$. Also note that

$$k \leq 187 d(\zeta_M) \leq 17952 n.$$ 

We claim that

$$\min_{W \in B(M, \phi)} \{\text{2-handle complexity of } W\} \geq \frac{k}{107712} - \frac{1}{2}.$$ 

To show the claim, suppose $W$ is a bordism over $G$ between $M = L(n, 1)$ and a trivial end. Then we can compute $\rho^{(2)}(M, \phi)$ as the $L^2$-signature defect of $W$. In particular, if $W$ has 2-handle complexity $r$, then $|\rho^{(2)}(M, \phi)| \leq 2r$. By the $L^2$-induction property and by Lemma 7.3 applied to the unknot, we have

$$\rho^{(2)}(M, \phi) = \rho^{(2)}(M, \text{id}_{\pi_1(M)}) = \frac{n}{3} + \frac{2}{3n} - 1.$$ 

Combining these, we obtain

$$r \geq \frac{n}{6} - \frac{1}{2} \geq \frac{k}{107712} - \frac{1}{2}$$

as claimed.

From the claim, it follows that

(7.6) $B^{2h}(k) \geq \frac{k}{107712} - \frac{1}{2}.$

Obviously $k \geq d(\zeta_M) \geq c(L(n, 1))$, and by Theorem 3.9, $c(L(n, 1)) \to \infty$ as $n \to \infty$. It follows that (7.6) holds for infinitely many $k$. This completes the proof. □
Appendix: simplicial sets and simplicial classifying spaces

In this appendix we give a quick review of basic definitions and facts on simplicial sets, for readers not familiar with them, focusing on those we needed in this paper, and present a detailed proof of Theorem 3.7 stated in the body. (See Proposition A.1.) There are numerous excellent references on simplicial sets. For instance, [May92], [GJ09] provide thorough extensive treatments, and [F Fi12] is an easily accessible introduction for non-experts.

§1. Simplicial sets and geometric realizations. We begin with a formal definition of a simplicial set. A simplicial set $X$ is a collection $\{X_0, X_1, \ldots\}$ of sets $X_n$ together with functions $d_i: X_n \to X_{n-1}$ ($n = 1, 2, \ldots, i = 0, \ldots, n$) and $s_i: X_n \to X_{n+1}$ ($n = 0, 1, \ldots, i = 0, \ldots, n$) satisfying the following:

$$
\begin{align*}
  d_id_j &= d_{j-1}d_i & \text{if } i < j, \\
  d_is_j &= s_jd_{i-1} & \text{if } i > j + 1, \\
  d_js_j &= s_{j-1}d_i & \text{if } i < j, \\
  s_is_j &= s_{j+1}s_i & \text{if } i ≤ j, \\
  d_js_j &= d_{j+1}s_i &= 1.
\end{align*}
$$

(A.1)

An element $\sigma \in X_n$ is called an $n$-simplex of $X$, and $d_i$ and $s_i$ are called the face map and degeneracy map. A simplex $\sigma \in X_n$ is called degenerate if $\sigma = s_i\tau$ for some $i$ and $\tau \in X_{n-1}$.

A morphism $f: X \to Y$ of simplicial sets is defined to be a collection of maps $f_0: X_0 \to Y_0$ satisfying $f_0d_i = d_i f$ and $f_0s_i = s_if$. Simplicial sets and their morphisms form a category, which we denote by $\textbf{sSet}$.

The underlying geometric picture is as follows. Define the standard $n$-simplex $\Delta^n$ to be the convex hull $[e_1, \ldots, e_n]$ of the standard basis in $\mathbb{R}^{n+1}$. Then the face map $d_i$ is an incarnation of taking the $i$th face $[e_1, \ldots, \hat{e}_i, \ldots, e_n]$ of $\Delta^n$ by omitting the $i$th vertex; similarly $s_i$ corresponds to producing a degenerate $(n+1)$-simplex $[e_1, \ldots, e_i, \ldots, e_n]$ from $\Delta^n$ by repeating the $i$th vertex. It is straightforward to verify the above relations of the $d_i$ and $s_i$ for the case of $\Delta^n$. As the key information of a simplicial set, the maps $d_i$ and $s_i$ indicate how the simplices are assembled in the geometric picture: for an $n$-simplex $\sigma$ and an $(n-1)$-simplex $\tau$, $d_i\sigma = \tau$ corresponds to an identification of $\tau$ with the $i$th face of $\sigma$, and similarly, $s_i\tau = \sigma$ corresponds to an identification of $\sigma$ with $\tau$ via a collapsing.

The above geometric idea is formalized to the following definition of the geometric realization $|X|$ of a simplicial set $X$. Let $D_i: \Delta^n \to \Delta^{n+1}$ be the $i$th face inclusion, i.e., the affine map determined by $(e_0, \ldots, e_n) \to (e_0, \ldots, \hat{e}_i, \ldots, e_n+1)$. Let $S_i: \Delta^{n+1} \to \Delta^n$ be the projection onto the $i$th face, i.e., the affine map determined by $(e_0, \ldots, e_{n+1}) \to (e_0, \ldots, e_i, \ldots, e_{n+1})$. Then

$$|X| := \left( \bigcap_{n \geq 0} X_n \times \Delta^n \right) / \sim,$$

where the equivalence relation $\sim$ is generated by $(\sigma, D_i(p)) \sim (d_i(\sigma), p)$ for $\sigma \in X_{n+1}$ and $p \in \Delta^n$, $(\sigma, S_i(p)) \sim (s_i(\sigma), p)$ for $\sigma \in X_n$ and $p \in \Delta_{n+1}$.

Due to Milnor [Mil57], the space $|X|$ is a CW-complex whose $n$-cells are in 1-1 correspondence to nondegenerate $n$-simplices of $X$: if $\sigma \in X_n$ is nondegenerate, the characteristic map of the corresponding $n$-cell (which we call an $n$-simplex of $|X|$) is given by

$$\varphi_\sigma: \Delta^n = \{ \sigma \} \times \Delta^n \hookrightarrow \bigcap_{n \geq 0} X_n \times \Delta^n \twoheadrightarrow |X|.$$

From this it follows that $|X|$ is a simplicial-cell complex in the sense of Definition 3.6 in the body of the paper.
A morphism \( f: X \to Y \) of simplicial sets gives rise to a continuous map \([f]: |X| \to |Y|\) induced by \( \{\sigma\} \times \Delta^n \xrightarrow{\text{id}} \{f(\sigma)\} \times \Delta^n:\)

\[
\begin{array}{c}
\{\sigma\} \times \Delta^n \\
\downarrow \text{id} \\
\{f(\sigma)\} \times \Delta^n \\
\downarrow \text{id} \\
\end{array}
\quad \begin{array}{c}
\coprod_{n \geq 0} X_n \times \Delta^n \\
\downarrow q \\
\coprod_{n \geq 0} Y_n \times \Delta^n \\
\downarrow q \\
\end{array}
\quad |X| \\
\quad |f| \\
\quad |Y|
\]

We remark that even when \( \sigma \in X_n \) is nondegenerate, \( f(\sigma) \in Y_n \) may be degenerate: \( q(\{f(\sigma)\} \times \Delta^n) \) may be a \( k \)-simplex in \( |Y| \) with \( k < n \).

From the above diagram, it follows that \(|f|\) is a simplicial-cellular map in the sense of Definition 3.6 in the body of the paper.

§2. Chain complexes. A based chain complex \( ZX_* \) called the (unnormalized) Moore complex is naturally associated to a simplicial set \( X \), similarly to the construction for an ordered simplicial complex: define \( ZX_n \) to be the free abelian group generated by \( X_n \), and define the boundary map \( \partial: ZX_n \to ZX_{n-1} \) by \( \partial(\sigma) = \sum_{i=0}^{n} (-1)^i d_i(\sigma) \) for an \( n \)-simplex \( \sigma \in X_n \). Then \( (ZX_*, \partial) \) becomes a based chain complex with the \( n \)-simplices as basis elements. This gives rise to a functor \( \text{sSet} \to \text{Ch}_k^\oplus \) into the category \( \text{Ch}_k^\oplus \) of positive based chain complexes.

We remark that the chain complex \( ZX_* \) of a simplicial set is distinct from the cellular chain complex \( C_*(|X|) := C_*(|X|) \) of its realization \( |X| \), since degenerate simplices are still generators of \( ZX_* \), while they do not give a cell of \( |X| \).

The chain complexes \( ZX_* \) and \( C_*(X) \) are related as follows. Let \( D_*(X) \) be the subgroup of \( ZX_* \) generated by degenerate simplices of \( X \), that is, simplices of the form \( s_1 \tau \) for some other simplex \( \tau \). It is known that \( D_*(X) \) is a contractible subcomplex and \( C_*(X) \cong ZX_*/D_*(X) \). Consequently we have a short exact sequence

\[
0 \to D_*(X) \to ZX_* \xrightarrow{p} C_*(X) \to 0
\]

where the projection \( p \) is a chain homotopy equivalence. We remark that the essential reason is that the \( n \)-cells of the CW complex \( |X| \) are in 1-1 correspondence with the nondegenerate \( n \)-simplices of the simplicial set \( X \). For a proof, see [May92, §22] or [ML95, p. 230].

We note that the projection \( p: ZX_* \to C_*(X) \) is a natural transformation between the functors \( \mathbb{Z}(-)_*, \text{sSet} \to \text{Ch}_k^\oplus \). That is, if \( \phi: X \to Y \) is a morphism of simplicial sets, then \( p \circ \phi = \phi \circ p \).

We also note that if \( X \) is an (ordered) simplicial complex which is viewed as a simplicial set, then \( C_*(X) \) can be viewed as a subcomplex of \( ZX_* \); for, in this case, the \( i \)th face \( d_i(\sigma) \) of a nondegenerate simplex \( \sigma \) is nondegenerate, and consequently the nondegenerate simplices generate a subcomplex of \( ZX_* \) which can be identified with \( C_*(X) \). We remark that it does not hold for an arbitrary simplicial set \( X \); as an exercise, such an example can be easily obtained using the simplicial classifying space \( BG \) discussed in §4.

§3. Products. One of the technical advantages of simplicial sets (in particular allowing degenerate simplices) is that the product construction is simple. For two simplicial sets \( X \) and \( Y \), \( X \times Y \) is defined by \( (X \times Y)_n := X_n \times Y_n \); together with \( d_i(\sigma, \tau) = (d_i(\sigma), d_i(\tau)) \) and \( s_i(\sigma, \tau) = (s_i(\sigma), s_i(\tau)) \), \( X \times Y \) becomes a simplicial set.
§4. Simplicial classifying spaces. Let $G$ be a group. The simplicial classifying space $BG$ is defined by the bar construction: $BG$ is the simplicial set with $BG_n = \{ [g_1, \ldots, g_n] \mid g_i \in G \}$ (in particular $BG_0 = \{ [] \}$ consists of one element) where the face map $d_i : BG_n \to BG_{n-1}$ and the degeneracy map $s_i : BG_n \to BG_{n+1}$ are given by
\[
d_i[g_1, \ldots, g_n] = \begin{cases} 
  [g_2, \ldots, g_n] & \text{if } i = 0, \\
  [g_1, \ldots, g_{i-1}, g_i, g_{i+1}, g_{i+2}, \ldots, g_n] & \text{if } 0 < i < n, \\
  [g_1, \ldots, g_{n-1}] & \text{if } i = n,
\end{cases}
\]
\[
s_i[g_1, \ldots, g_n] = [g_1, \ldots, g_i, e, g_{i+1}, \ldots, g_n].
\]

From the definition, it is straightforward to verify that $B : \mathbf{Gp} \to \mathbf{sSet}$ is a functor of the category of groups $\mathbf{Gp}$. It is well known that the geometric realization $|BG|$ of $BG$ is an Eilenberg-MacLane space $K(G, 1)$.

In the following statement, $\pi_1(A)$ of a space $A$ is understood as the free product of the fundamental groups of the path components.

**Proposition A.1.** Suppose $X$ is a simplicial set and $\phi : \pi_1(|X|) \to G$ is a group homomorphism. Then there is a morphism $f : X \to BG$ of simplicial sets such that $[f]_* : \pi_1(|X|) \to \pi_1(|BG|) = G$ is equal to $\phi$.

We remark that Theorem 3.7 in the body of the paper is an immediate consequence of Proposition A.1.

**Proof of Proposition A.1.** We will define $f$ on $X_n$ inductively and check the functoriality $d_i f = f d_i$ and $s_i f = f s_i$ at each step.

We start by defining $f$ on $X_0$ by $f(v) = [[]] \in BG_0$ for any $v \in X_0$. For each 0-simplex $v$ of $X$, choose a path $\gamma_v$ to it from the basepoint of its component in $|X|$. (For example one may take a spanning forest of the 1-skeleton to determine the $\gamma_v$.) For $\sigma \in X_1$ from $w := d_1 \sigma$ to $v := d_0 \sigma$, we define
\[
f(\sigma) = [\phi(\gamma_w \cdot \psi_{\sigma} \cdot \gamma_v^{-1})] \in BG_1.
\]
We have that $f(d_i \sigma) = [[]] = d_i f(\sigma)$ for $\sigma \in X_1$, and $f(s_i \tau) = s_i [[]] = f(\tau)$ for $\tau \in X_0$. Also note that $f(\sigma) = [e]$ when $\sigma$ is a degenerate 1-simplex (that is, $\sigma = s_i \sigma'$ for some $\sigma' \in X_0$).

For notational convenience, for $\sigma = [g_1, \ldots, g_k] \in BG_k$ we often denote by $\sigma$ the sequence $g_1, \ldots, g_k$ by removing the brackets. In particular if $\sigma \in BG_k$ and $\tau \in BG_{k+\ell}$, then $[\sigma, \tau]$ denotes an element in $BG_{k+\ell}$.

For $\sigma \in X_2$, define
\[
f(\sigma) = [f(d_2 \sigma), f(d_0 \sigma)] \in BG_2.
\]
Note that we have $f(d_0 \sigma) \cdot f(d_1 \sigma)^{-1} : f(d_2 \sigma) = e$ in $G$ since $\partial \sigma = d_0 \sigma - d_1 \sigma + d_2 \sigma$. Using this we check the functoriality: for $\sigma \in X_2$ and $\tau \in X_1$,
\[
d_0 f(\sigma) = d_0 [f(d_2 \sigma), f(d_0 \sigma)] = [f(d_0 \sigma)] = f(d_0 \sigma),
\]
\[
d_1 f(\sigma) = d_1 [f(d_2 \sigma), f(d_0 \sigma)] = [f(d_2 \sigma) f(d_0 \sigma)] = [f(d_1 \sigma)] = f(d_1 \sigma),
\]
\[
d_2 f(\sigma) = d_2 [f(d_2 \sigma), f(d_0 \sigma)] = [f(d_2 \sigma)] = f(d_2 \sigma),
\]
\[
f(s_0 \tau) = [f(d_2 s_0 \tau), f(d_0 s_0 \tau)] = [f(s_0 d_1 \tau), f(\tau)] = [e, f(\tau)] = s_0 f(\tau),
\]
\[
f(s_1 \tau) = [f(d_2 s_1 \tau), f(d_0 s_1 \tau)] = [f(\tau), f(s_0 d_0 \tau)] = [f(\tau), e] = s_1 f(\tau).
\]

In general, suppose $f$ has been defined on $X_k$ for $k < n$. For $\sigma \in X_n$ we define $f$ by
\[
f(\sigma) = [f(d_n \sigma), f(d_{n-1} \sigma)].
\]
We claim that
\[(A.3)\]
\[f(\sigma) = [f(d_2 \cdots d_n \sigma), f(d_0 \sigma)].\]
For, it obviously holds when \(n = 2\); for \(n > 2\), using \((A.2)_{n-1}\) and \((A.3)_{n-1}\) as induction hypotheses, we obtain
\[
f(\sigma) = [f(d_2 \cdots d_{n-1} \sigma), f(d_0 d_n \sigma), f(d_0^{n-1} \sigma)] \quad \text{by} \quad (A.2)_{n-1},
\]
\[
= [f(d_2 \cdots d_{n-1} d_n \sigma), f(d_0 d_n \sigma), f(d_0^{n-1} \sigma)] \quad \text{by} \quad (A.3)_{n-1},
\]
\[
= [f(d_2 \cdots d_{n-1} d_n \sigma), f(d_0 \sigma)] \quad \text{by} \quad (A.1).
\]

Now using \((A.1), (A.2), \) and \((A.3)\) we verify the functoriality: for \(\tau \in X_n, \) if \(i < n - 1, \) we have
\[
d_i f(\sigma) = d_i[f(d_2 \cdots d_n \sigma), f(d_0^{n-1} \sigma)] = [d_i f(d_n \sigma), f(d_0^{n-1} \sigma)]
\]
\[
= [f(d_i d_n \sigma), f(d_0^{n-1} \sigma)] = [f(d_n d_i \sigma), f(d_0^{n-1} \sigma)] = f(d_i \sigma),
\]
and if \(i > 1, \) we have
\[
d_i f(\sigma) = d_i[f(d_2 \cdots d_n \sigma), d_0 \sigma)] = [d_i f(d_2 \cdots d_n \sigma), d_0 \sigma]
\]
\[
= [f(d_2 \cdots d_n \sigma), f(d_0 d_i \sigma)] = [f(d_2 \cdots d_n d_i \sigma), f(d_0 \sigma)] = f(d_i \sigma).
\]
So, in any case, we have \(d_i f(\sigma) = f(d_i \sigma). \) Also, for \(\tau \in X_{n-1}, \) if \(i < n - 1, \) we have
\[
s_i f(\tau) = s_i[f(d_{n-1} \tau), f(d_0^{n-2} \tau)] = [s_i f(d_{n-1} \tau), f(d_0^{n-2} \tau)]
\]
\[
= [f(s_i d_{n-1} \tau), f(d_0^{n-2} \tau)] = [f(d_n s_i \tau), f(d_0^{n-1} s_i \tau)] = f(s_i \tau),
\]
and if \(i > 0, \) we have
\[
s_i f(\tau) = s_i[f(d_2 \cdots d_{n-1} \tau), f(d_0 \tau)] = [f(d_2 \cdots d_{n-1} \tau), s_i f(d_0 \tau)]
\]
\[
= [f(d_2 \cdots d_{n-1} \tau), f(s_i d_0 \tau)] = [f(d_2 \cdots d_{n-1} \tau), f(d_0 \tau)] = f(s_i \tau).
\]
This completes the proof that \(f: X \to BG\) is a well-defined morphism of simplicial sets.

From the definition of \(f\) on \(X_1,\) it follows that \(f\) induces the given homomorphism \(\phi: \pi_1(|X|) \to G.\) \(\square\)
